"You may have received an email telling you that your cell phone is about to be assaulted by telemarketing calls as a result of a new cell phone number database; however, that is not the case. FCC regulations prohibit telemarketers from using automated dialers to call cell phone numbers. Automated dialers are standard in the industry, so most telemarketers don't call consumers on their cell phones without their consent."

2357. W7EL's Food for Thought: Forward and Reverse Power

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-18 15:13:38 UTC
From: Cecil Moore <nospam@w5dxp.com>
Message-ID: <Bghuj.925$pl4.352@newssvr22.news.prodigy.net>
Source record: 27979

While working on an energy-based presentation of W7EL's
data from the following web page, I came across an
instance where my energy analysis differed from W7EL's
results under the "Food for Thought: Forward and Reverse
Power" section. Assuming Roy was correct, I attempted to
find my error and failed to do so.

http://eznec.com/misc/Food_for_thought.pdf

**********begin quote**********

Zl fPa rPa Pa(tx) Pa(src) Pa(R0) Pa(Rl) frac R0 frac Rl
0 + j0 100 100 0 0 0 0 - -
infinite 100 100 0 0 0 0 - -

Not only that, but notice the last two cases. Here, the reverse power is
a full 100 watts. The source match is 1:1. Yet *none* of this reverse
power is dissipated in the source resistance. In fact, no power at all
is dissipated in the source resistance.

ANY MODEL PRESENTED TO ACCOUNT FOR WHAT HAPPENS TO "FORWARD" AND
"REVERSE" POWER AT TRANSMISSION LINE ENDS HAD BETTER GIVE RESULTS THAT
AGREE WITH THE ABOVE TABLE.

**********end quote**********

Unfortunately, my results do not agree.

In the line where ZL is zero, i.e. a short-circuit, the
dissipation in the source resistance is 400 watts, i.e.
all of the forward power and reflected power is dissipated
in the source resistor plus an additional 200 watts associated
with constructive interference. All 400 watts must be supplied
by the source so Pa(src) must also be 400 watts. It should read:

Zl fPa rPa Pa(tx) Pa(src) Pa(R0) Pa(Rl) frac R0 frac Rl
0 + j0 100 100 0 400 400 0 1.0 -
infinite 100 100 0 0 0 0 - -

For the ZL=0 case:
Pa(R0) = fPa + rPa + 2*SQRT(fPa*rPa) = 400 watts
This is *total constructive interference* as defined by
Hecht in "Optics".

For the ZL=infinite case:
Pa(R0) = fPa + rPa - 2*SQRT(fPa*rPa) = 0 watts
This is *total destructive interference* as defined by
Hecht in "Optics".

Since Roy doesn't read my postings or emails, could someone
please pass this information on to him.

Jimmie D wrote:
"The book shows a .25wl of antenna and a .25wl of stub,---."

The J antenna is often described as a half-wave of antenna with a quarter-wave matching stub.

Function of the stub is to shunt the antenna at a point so that the parallel combination of antenna and stub equal Zo.

If the antenna were only 1/4-wavelength, reflection from its open-circuit end at its drive point may yet be compensated by a .25wl stub.

At the 1/4-wavelength stub`s short-circuit, phase of the reflected voltage is reversed. Voltage reflected from the open-circuit tip of the antenna is not reversed in phase by its reflection. Both waves travel the same distance to the point where they meet at the antenna drive point. These tend to offset each other.

Terman describes impedance matching using stubs on page 109 of his 1955 opus:
"Thus, although a reflected wave is present in the length l1 because of reflection from ZL, there is no reflected wave on the generator side of the stub line as a result of the cancellation of the two reflected waves."

Best regards, Richard Harrison, KB5WZI

Why did you bother with Hecht? It's simple enough to go back to the second equation above the line you disagree with, the one at the bottom of page 7 in that pdf, and see it does not agree there either. It's obviously a typo and should be corrected. I'll drop Roy a line about it, in case he doesn't see this.

Cheers,
Tom

The actual calculation for a practical situation isn't simple--or perhaps I should say isn't easy for a human to do. It's the sort of thing we'd most likely let a computer do these days. But you can at least get an idea about what's going on. The characteristics of a material that will interact with radio waves--electromagnetic radiation--are its permeability, permittivity, and resistivity. Permeability relates to magnetism, and for non-ferromagnetic materials, you probably don't have to worry much about it. As a start, you might have a look at Wikipedia for permittivity, or do a google it. The Wikipedia article I found about it looked pretty reasonable.

Yours is a good question. Some people make a career out of studying that sort of thing and becoming experts in it. You'd probably need to study "electricity and magnetism" up through a good understanding of Maxwell's equations and then get into the details of the physical properties of materials to thoroughly understand it. Even then, there'd be lots of puzzles to figure out, if you wanted. In other words, you can dive pretty deeply into it if you want. But you're absolutely right, the properties change with frequency, and the effects you'd see at different frequencies would be different even if the properties were to stay the same.

Cheers,
Tom

No, it would vaguely appear as I discribed with exceptions. They are
simular. The antenna I was talking about is shunt fed and the open sleeve is
series fed and the stub elements are much closer together than on the open
sleeve. This would never work on both both 14 and 28 as the open sleeve is
ment to do. Then again a J pole has always been a variant of a sleeve
antenna.

Yes, I know . The thing that threw me was that a ran the numbers for a 10M j
the ones that are normally 3/4 wl long overall. To my surprise the 50 ohm
point where you connected the feedline to stub was in the same place on both
antennas. Initial assumption was this was some kind of screw up. I guess
not. This AM I spent some time building the short J out of some galvanize
pipe and it works as advertise

Hi Jimmie,

That would make sense given the matching section is to match a 50 Ohms
drive to any load.

>Initial assumption was this was some kind of screw up. I guess
>not. This AM I spent some time building the short J out of some galvanize
>pipe and it works as advertise

If you are still talking about the curiosity of a quarterwave match to
a quarterwave radiator, then it should work as advertised. The
curiosity factor is like wondering why anyone would buy a car with
five wheels when the world has been traveling on four for millennia.

Some users think they are doing those of us who are interested in antennas a favor by posting what they think are useful topics - something "everyone needs to know." Sometimes it is cellphone do not call lists. Other times it is some PC virus, etc. etc. Usually it is bogus information that the original poster was misled into believing, and ends up costing all of us wasted time. There are tens of thousands of newsgroups where these topics can be discussed.
When I enter rec.radio.amateur.antennas all I want to see is stuff about antennas.
Hey Guys, I value my time so much that I measure it in milliseconds.
I constantly update my kill file with posters who aren't really interested in antennas (Art), and subjects that have gotten so far off the topic of antennas that they are also a waste of my milliseconds.

Yuri can stay. Roy Lewallen can stay. Richard Clark and Cecil can stay.
THOSE guys know antennas. The rest of you are on probation.

Hi Mike,

It would be far more interesting to figure out why for 12 years the
whining Republicant-get-dones never took care of:
1. An amendment to protect the flag;
2. A balanced budget;
3. A great reputation overseas;
4. A secure Nation (how many years on orange alert?);
5. Fixed or eliminated the Capital Gains Tax;
6. Building more refineries;
7. Cut backs on government bureaucracy;
8. Getting out of local Schools;
9. Unfunded mandates;
10. The deficit;
11. An economy that won't tank every 2 years;
12. The infrastructure;
13. Getting out of "nation building" (a crapola idea);
14. Handing the country over to the Chinese communists;
15. Taking care of the midget in North Korea;
16. Taking care of the midget of Cuba's Castro;
17. Taking care of the midget of Venezuela's Hugo Chavez;
18. Taking care of the midget Qadaffi;
19. Taking care of the midget in NW Pakistan Ossama been Forgotten;
20. Our brave commie allie, Putin;
21. Getting back the canal;
22. Stopping the flow of illegals (the raging Republicant-get-done
issue of 1988).....

and on an on and on.

Myron;

The only problem with your insulators is that the tree is alive and
still growing. It will eventually grow around the insulator and embed it
in the wood. This will take a long time but they are still finding
cannon balls in trees left over from the Civil War.

Cecil;

Good point. Also remember that for all the billions of dollars spent on the space program and going to the Moon there is not one single doller bill on the moon or in space except for some personal cash taken by an enterprising astronaut or cosmonaut looking to make a quick profit.

Bob;

Attenuation can be a problem but not until frequencies reach the Ghz
range. Then it is a case of radiated signal being reflected not absorbed
by the intervening material. i.e. wood will absorb, radome plastic will
transfer.

As for a source of information, all I can suggest is GOOGLE.

Your current building master antenna will still function exactly as it
is currently doing the only change is the mode of the signal from analog
to digital.

Some times its just plain old spam, or postings from the fringe elements
of the newsgroups.

> When I enter rec.radio.amateur.antennas all I want to see is stuff about
> antennas.

That would be cool wouldn't it? Isn't going to happen.

Maybe you could start a yahoo or google group, moderate it, and no
posts other than what you want to see will show up.

> Hey Guys, I value my time so much that I measure it in milliseconds.
> I constantly update my kill file with posters who aren't really interested
> in antennas (Art), and subjects that have gotten so far off the topic of
> antennas that they are also a waste of my milliseconds.

I feel pretty unimportant now, My time management dictates only goes to
increments of 500 milliseconds. ;^)

But seriously, that is what killfiles or filters are for. Don't want to
see someone, and at least in my software, I push "k", and its TTFN!

> Yuri can stay. Roy Lewallen can stay. Richard Clark and Cecil can stay.
> THOSE guys know antennas. The rest of you are on probation.

Why do people come into groups, and set themselves up as the cops? Who
are you to determine who stays and who is on "probation". When people
write stuff such as this, they have an implicit sense of entitlement, as
if Roy, Richard, and Cecil owe you edification. They don't. You really
need your own group, and you can invite the chosen few, and you can
disallow any posts you determine to be off topic. Don't be surprised if
they don't show up though.

For that matter, will you allow posts by Cecil when he goes off on a
cosmology tangent (often with me along) or Richard when he treats us to
one of his amusing forays?

I'd be pleased to be in your plonkfile. Note, I post from two separate
accounts, so you'll have to do two filters so that I don't pollute your

screen.

Cecil, W5DXP wrote:
"What ? "Cancellation of the two reflected waves"??? Some of the gurus here say that cannot happen, that there is never any interaction between waves."

I was quoting Terman word for word. In more than 60 years of studying him I have never found him mistaken. Terman uses words like cancellation, waves, and power. These words make me comfortable even when I don`t understand what was said upon first reading.

On the subject of the Flagpole J, Kraus has some words on matching with a short-circuited 1/4-wave stub on pages 719 and 720 of his 3rd edition. These reminded me of a conversation with Charlie Wright of A.D. Ring & Associates I had over 50 years ago. Although Kraus had already published, we didn`t have his book.

Kraus writes:
"A modification of this antenna is shown at (e) in which a short-circuited 1/4-wave section of coaxial line is connected in parallel with the antenna terminals. This widens the impedance bandwidth and also places the stub antenna at ground potential. This is desirable to protect the transmission line from lightning surges."

From experience, Kraus has proved to be correct and you can bank on what he says. Frequency agile amateurs find resonant lengths of transmission line troublesome at times, but more bandwidth over a narrow range and protection from lightning are big assets where needed.

Best regards, Richard Harrison, KB5WZI

Hi Rick,

Your comment is duly noted (some might dispute the last statement). As
for being trapped, I exult in it (nothing easier than shoving a sharp
elbow into the soft doughy ribs of a fat decadent Republicant).

I've no problem with off-topic posts as the days of 1200 Baud
downloads have long slipped beneath the goo of LaBrea. The modern
miracle of killfiles for threads and authors easily takes care of the
static that sometimes floods the group (in fact, I have very few of
them - mostly oriented towards the CB/SW cross-posted fanatics that
are geared up solely for trolling). I've seen fellows complain about
a flood of M.I.6 postings, but I've never seen the original posts
except once to add the filters. Complaining is a sport here in its
own right where the solution is so obvious.

Being On Topic has no correlation to quality, unfortunately. Where
the author is overly repetitive - and we have several longstanding
contributors - I simply read one in maybe a dozen posts from them to
confirm, yes, more boring repetition. That trade in technical
pornography finds no censors calling for their abolition. It easily
surpasses Off Topic discussion and is an effluent that dilutes serious
correspondence overwhelmingly. But whatchagonnado?

However, within that drek there is sometimes either a remarkable
question, or a remarkable gaff that reveals an interesting turn. Then
there are trolls disguised as "remarkable" questions - such as this
thread and Dan's submergence into the shadows of anonymity to both
continue his sniping while giving the patrician appearance of having
departed this sewer in a moral outrage of disgust.

Heck, even your posting complaining about Off Topic discussion constitutes Off Topic discussion (amazing paradox about this that must have had the philosophers scratching their heads some dozen centuries ago).

It would be interesting to find a tangent point for the cosmos but
that would involve going off on a 4 dimensional cosmological tangent.

Greetings,

I had a horizontal loop antenna up for several years prior to my
moving to Texas. It was cut for 80 meters and was about 30 feet up in
a square configuration.

I fed it with coax to one corner, however I had a homebrew choke at
the connection point. I used a 10" long piece of 6 inch pvc pipe with
about 10 turns of coax around it.

The antenna worked fairly well and by virtue of the design loops are
pretty quiet.

You mention 400 feet on your loop. The formula I used was 1005/
frequency = feet in loop.

There is a yahoo group devoted to skywire loop antennas and some good
info can be found there.

At the present time I'm getting ready to erect an 80 meter loop, but
this one will be fed with 600 ohm homebrewed ladder line into a
Palstar balanced wire tuner. I'm anxious to get this on the air.

2396. Looking for an old project based on two half wave vertical dipoles by W7DE...

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-18 21:56:36 UTC
From: "Francesco L." <franlanc@NOSPAMtin.it>
Message-ID: <61ud5tF1vvokuU1@mid.individual.net>
Source record: 27918

Some years ago I used to buy 73 when it was available in my hometown in Italy. I mostly liked antenna projects and ardf articles. Once I saw an HF antenna called "the palm phased array", the "California phased array" or something like that, engineered by Dave Evison W7DE. It was based on two vertical dipoles strung onto two palm trees. Is there any source where I can find this project? Thanks a lot for any help, it would be useful.

Thanks very much to both Cecil, for finding the error, and Tom, for passing it along.

Tom is correct, that the information in the table should follow directly from the equations at the bottom of the preceding page. The table entry was in error, but not the equations or underlying principles. For Rl = 0 + j0 the equation at the bottom of page 7

Pa(R0) = |Ilrms|^2 * R0 = (Vrms^2 * R0) / [(R0 + Rl)^2 + Xl^2]

gives the correct result of 400 watts, not 0 as shown in the table. The table has been corrected, and the comments following it have been modified to reflect the corrected value. Here's the corrected table and text:

****

Zl fPa rPa Pa(tx) Pa(src) Pa(R0) Pa(Rl) frac R0 frac Rl
50 + j0 100 0 100 200 100 100 0.50 0.50
100 + j0 100 11.1 88.9 133 44.4 88.9 0.33 0.67
25 + j0 100 11.1 88.9 267 178 88.9 0.67 0.33
37 +/-j28(*)100 11.4 88.6 209 120 88.6 0.58 0.42
0 +/-j50 100 100 0 200 200 0 1.00 0
0 +/-j100 100 100 0 80.0 80.0 0 1.00 0
0 + j0 100 100 0 400 400 0 1.00 0
infinite 100 100 0 0 0 0 - -

(*) For any Zl that causes exactly a 2:1 SWR, rPa will equal 11.1 and Pa(Rl) = 88.9. The values shown for 37 +/-j28 are slightly different because this impedance doesnï¿½t result in quite exactly a 2:1 SWR.

For the second, third, and fourth entries, the SWR is 2:1. The forward and reverse powers are the same for all three, and the source impedance (50 ohms) is the same for all the above cases. So here we have three cases where the reverse powers are the same, and the impedance match looking back toward the source is the same (1:1), yet the dissipation in the source resistor Pa(R0) is very different. The obvious conclusion is that THE POWER DISSIPATED IN THE SOURCE RESISTANCE ISNï¿½T DETERMINED DIRECTLY BY THE SOURCE MATCH, THE SWR, OR THE REVERSE POWER. Otherwise it would be the same in all three cases, since all these quantities are the same for all three.

For the last four entries, the SWR is infinite, and the reverse power is a full 100 watts. The source is perfectly matched to the line for all table entries. Yet the source resistor dissipation varies from 0 to 400 watts depending on the load impedance ï¿½ despite no difference in source match, or forward or reverse power for the four entries.

The last two entries are particularly interesting. When the line is open circuited at the far end (last table entry), there is no power at all dissipated in the source resistor. So none of the reverse power is dissipated in the source resistor. Yet when the line is short circuited at the far end (next to last table entry), the source resistor dissipates twice the sum of the forward and reverse powers.

From the last entry alone we can conclude that THE REVERSE POWER IS NOT DISSIPATED IN OR ABSORBED BY THE SOURCE RESISTANCE. And the table clearly shows that the source resistor dissipation bears no relationship to the amount of reverse power.

****

The corrected essay has been uploaded to replace the previous one at http://eznec.com/misc/Food_for_thought.pdf. Please note the uppercase "F" -- it has to be entered exactly as shown.

Again, thanks very much for the corrections. It's my sincere intention to present material that's accurate, and I appreciate the help in finding and correcting errors I've made.

Such is the nature of *total destructive interference* as
described by Hecht in "Optics". All of the reflected energy
is redistributed back toward the load.

> Yet when the line is short circuited
> at the far end (next to last table entry), the source resistor
> dissipates twice the sum of the forward and reverse powers.

Such is the nature of *total constructive interference* as
described by Hecht in "Optics". All of the reflected energy
plus some more supplied by the source is dissipated in the
source resistor.

> From the last entry alone we can conclude that THE REVERSE POWER IS NOT
> DISSIPATED IN OR ABSORBED BY THE SOURCE RESISTANCE.

Of course not from only the last entry when total destructive
interference is occurring. 100% of the reflected energy is
redistributed back toward the load.

OTOH, when total constructive interference is occurring, not
only is 100% of the reflected energy dissipated in the source
resistor but the source has to supply twice as much energy as
the forward power plus the reflected power combined.

Perhaps the following energy analysis will shed some light on
the misconceptions. "Shedding some light" seems appropriate
since these concepts are from the field of optical physics.

This posting will provide an energy analysis approach to the
same previous W7EL data specifically avoiding any reference
to voltage and current.

The example that Roy provided in ï¿½Food for Thought: Forward
and Reflected Powerï¿½ is:

```
Rs
+----/\/\/-----+----------------------+
| 50 ohm |
| |
Vs 1/2 wavelength ZLoad
141.4v 50 ohm line |
| |
+--------------+----------------------+
```

http://eznec.com/misc/Food_for_thought.pdf

We will create a new chart, step by step, that doesn't use voltages or currents. Note that the first two columns are copied from W7ELï¿½s chart. The Gamma reflection coefficient is calculated at the load and |Rho|^2 is the power reflection coefficient. The reflected power is the forward power multiplied by |Rho|^2. 'GA' is the reflection coefficient Gamma Angle.

Zl fPa Rho GA,deg |Rho|^2 rPa
1. 50 + j0 100 0.0 0 0.0 0
2. 100 + j0 100 0.3333 0 0.1111 11.1
3. 25 + j0 100 0.3333 180 0.1111 11.1
4. 37 +/-j28 100 0.3378 97.1 0.1141 11.4
5. 0 +/-j50 100 1.0 -90 1.0 100
6. 0 +/-j100 100 1.0 -53.2 1.0 100
7. 0 + j0 100 1.0 -180 1.0 100
8. infinite 100 1.0 0 1.0 100

So far, everything agrees with W7ELï¿½s chart. We will now use the following power equation not only to predict the dissipation in the source resistor but also to explain the redistribution of energy associated with interference. The power equation is:

Pa(R0) = fPa + rPa + 2*(fPa*rPa)cos(180-GA)

Where 'GA' is the reflection coefficient Gamma angle and the last term, 2*SQRT(fPa*rPa)cos(180-GA), is known as the *INTERFERENCE TERM*.

fPa rPa (180-GA) Pa(R0) interference term
1. 100 0 180 100 0
2. 100 11.1 180 44.4 -66.7
3. 100 11.1 0 177.8 +66.7
4. 100 11.4 82.9 119.8 + 8.35
5. 100 100 270 200 0
6. 100 100 233.2 80.2 -119.8
7. 100 100 360 400 +200
8. 100 100 180 0 -200

Except for the error that W7EL made in the Pa(R0) for example number 7, these values of Pa(R0) agree with W7ELï¿½s posted values. Therefore, the power-interference equation works. Not only does it work, but it tells us the magnitude of interference between the forward wave and the reflected wave when they interact at the source resistor. Line by line:

1. There is zero interference because there are no reflections.

2. There is 66.7 watts of destructive interference present.

3. There is 66.7 watts of constructive interference present.

4. There is 8.35 watts of constructive interference present.

5. There is zero interference because the forward wave and
reflected waves are 90 degrees apart.

6. There is 119.8 watts of destructive interference present.

7. There is 200 watts of constructive interference present.

8. There is 200 watts of destructive interference present.
All of the reflected energy is redistributed back toward the load.

Wonder no more where the power goes. Constructive interference
requires extra energy from the source. Destructive interference
redistributes some (or all) of the reflected energy back toward
the load. Under zero interference conditions, all of the reflected
power (if it is not zero) is dissipated in the source resistor.

I once thought that would work, and even helped a little with an Antenna Compendium article promoting it a long time ago. But I came to realize that it doesn't matter at all whether the balun is at the input or output of the tuner -- the balun is just as effective one place as the other. The reason is that what counts is the common mode impedance, which is the impedance to ground seen looking along the outside of the coax toward the antenna, and this is the same on both sides of the tuner (except, of course, for the difference due to the short distance between the two points). Putting the balun the input has the disadvantage of making the tuner chassis hot.

I'm sorry to see that QST's article review process still isn't working.

Hey Richard, getting back on topic. I haven't yet heard of a good justification of the SPT other than some general sentiments about how we need to spend money on science which has been, usually, a sound investment. The HAARP antenna project for example has a defined purpose. The moon exploration had a defined purpose. But what is the exact purpose of THIS white elephant? That is really what my comments were related to. If you try to find the purpose you will see a confusing conglomeration of attempts to understand microwave cosmic rays and even exotic physics which are unlikely to be confirmed empirically. Really, take a look at the white papers on google. In reality, NSF has a budget. NSF MUST expend the budget or guess what, they risk getting less money next year. That is how government agencies work. NSF must be running out of ideas. They cannot think of anything that has more direct benefit in understanding the universe than constructing a telescope in the South Pole. I would think the hubble is suffiently far from city lights and could do a much better job. Finally Rich, you might try expending less effort on analyzing the motivations as to why certain people write the things they do and more effort on the technical content of what is being said. Just a suggestion.

Bruce W. Ellis wrote:
"I am considering a horizontal loop antenna that would be "squarish"
(depending on the tree locations) and about 400` in circumference."

If you had more trees (octagonalish) would enclose more area with the
same wire. Radiation is a function of loop area.

Tesonant loops are often one wavelength in perimeter. 400` is about 122
meters. 160 meters = 525 feet. 80 meters = 262 meters. What band do you
prefer? If a loop`s perimewter is a little too short for resonance, it`s
inductive and can be tuned with a low-loss variable capacitor.

The 20th edition of the ARRL Antenna Book has a horizontal loop
"skywire" (squarish) on page 5-20. A 7 MHz loop at 40 ft. elevation has
about the same radiation as a 7 MHz dipole at 30 ft. elevation for
various azimuths. It might be worthwhile reading the Antenna Book
article before construction.

Best regards, Richard Harrison, KB5WZI

Can you please explain that a little more? If you put 100 watts into a 400 foot circumference loop and it radiates 95 watts, will an 800 foot loop radiate four times that, or 380 watts? Then can you feed back 100 to put back into the loop, and have 280 left over to run your refrigerator to keep your beer cold?

Or if the 800 foot loop radiates 95 of your 100 watts, does the 400 foot loop radiate only 23.75 watts? If that's what happens, where does the rest of the power go?

Is the radiation pattern the same for a long skinny loop as for a round one, as long as the enclosed area is the same?

Hi Dan,

I might if I weren't so provided with the amusing irony of your own
analyzing motivation. Technical content? The topic is coy troll that
has long died on its feet from intellectual anemia. The best you have
to offer is sputtering along with cartoon dialog in an attempt to
breath life into its corpse. Such effort is as entertaining as
uninspired clog dancing.

>

hmmm that's not entirely true in my experience. One year I made a 4
elements quad for the 50 MHz band, simulated with nec using bare wires
and no boom, then built with metallic boom (and insulated wire spokes
of course) and with insulated wires, same diameter as in the
simulation. The result was so badly detuned that it actually had more
gain in the back direction than the forward one, SWR was like 3:1.
Probably the effect was due to insulated wire, but never investigated
further, I just dismantled it and built an 8 element yagi instead.
So far though nobody answered my original question as wether unaligned
driven element on yagis will have or not effects on tuning/
performance.

Sounds like a Franklin antenna, also known as a colinear array. Vertical radiation pattern from a radiator that grows beyond 180-degrees starts producing an undesired high-angle lobe in addition to the signal radiated at low angles to the earth`s surface. The undesired radiation is produced when current in the radiator reverses direction at the 180-degree mark. If we introduce a phase inverting device at the 180-degree mark on the radiator we increase radiation perpendicular to the longer radiator without growing a high-angle lobe.

Many VHF colinear antennas use 1/4-wave stubs as phase inverters between 1/2-wave radiating sections. A resonant L-C circuit can be used in place of a 1/4-wave short-circuit stub. A transformer can also be used to reverse the phase as can various line feeds.

In the "International" edition or 3rd edition of Kraus` "Antennas" on page 824 in Fig. 23-21(b) is shown a dipole made of (4) 1/2-wave sections. It uses (2) self-resonant coils. Each coil separates a pair of 1/2-wave radiators so that all four radiators have current flowing in the same direction through them at the same time.

Everyone needs access to the newest 3rd edition of "Antennas".

Best regards, Richard Harrison, KB5WZI

Richard, that graphic is redrawn on my web page at:

http://www.w5dxp.com/current.htm

The first two sections of that page are quotes from "Antennas"
by Kraus. The second section illustrates the above antenna.
And I don't think Kraus was using the lumped circuit model for
those coils. :-)

Not being a typist, I`ll refer you to "TV And Other Receiving Antennas" by Arnold Bailey. On pages 407 and 408 Bailey gives two formulas for computing the antenna resistance for a loop antenna.

On page 408, Bailey has Fig. 8-14 which plots radiation resistance (the stuff we build antennas for) versus the loop perimeter in wavelengths. For a square closed loop of one wavelength perimeter, the graph indicates about 50 ohms.

Bill Orr, W6SAI in "All About Cubical Quad Antennas" gives the full-wave vertical loop antenna an impedance of 125 ohms on page 15.

On page 14, Orr writes:
"For purposes of illustration, the two wire folded dipole may be "pulled open" to a diamond-shaped loop fed at the bottom point. If this distortion of the loop is continued the antenna will become a shorted transmission line."

A perfect circle is the geometric shape enclosing the most area for a given perimeter. The more corners a closed figure has, the more closely it usually approximates a circle. That is why I commented on an octagon versus a square.

Best regards, Richard Harrison, KB5WZI

Back on topic! Sort of! Did anyone catch the story today about the new Chinese Astronomical Observatory near the South Pole? The story is from the New York Times and the writer states the observatory is 700 miles East of the South Pole! That statement is repeated again in a picture.

Now, isn't that a good test for graduates of the American Education system? Fortunately, the writer is working for a newspaper and not somewhere important.

Paul

Could you expand on why the expression on the right is equal to
the average power dissipated in R0(Rs)? How was the expression
derived?

As well, what would be the equivalent expression for the following
example?

+-------+-------------+----------------------+
| | |
^ | Rs |
Is +-/\/\/-+ 1/2 wavelength ZLoad

```
2.828A 50 ohm | 50 ohm line |
| | |
+---------------+-----+----------------------+
```

The forward power is the same, the source impedance is the same,
but the conditions which cause maximum dissipation in the source
resistor are completely different.

Why is it not the same expression as previous since the conditions
on the line are the same?

What is the expression that describes the power dissipated in the
source resistor?

How is the expression derived?

I'm missing something here. I don't see anywhere in the response which explains how "radiation is a function of loop area" and why increasing the loop circumference would be advantageous.

Perhaps you build antennas for radiation resistance, but I think most people build them to maximize radiation in some direction. In any case, please exclude me from the "we" in your statement about what "we" build antennas for. You said "radiation is a function of loop area" and recommended a larger circumference. Equations are useless unless you understand how to apply them. So can you use those equations to show us how much more a loop of 800 foot circumference will radiate than one with a 400 foot circumference? You can assume 100 watts applied to each, and either zero wire resistance or any reasonable value.

Opps, sorry - a typo. That equation should be:

Pa(R0) = fPa + rPa + 2*SQRT(fPa*rPa)cos(180-GA)

> Could you expand on why the expression on the right is equal to
> the average power dissipated in R0(Rs)? How was the expression
> derived?

This is essentially the same as the irradiance-interference
equation from optical physics. It's derivation is covered
in detail in "Optics" by Hecht, 4th edition, pages 383-388.
It is also the same as the power equation explained in detail
by Dr. Steven Best in his QEX article, "Wave Mechanics of
Transmission Lines, Part 3", QEX, Nov/Dec 2001, Eq 12. It
can also be derived independently by squaring the s-parameter
equation: b1^2 = (s11*a1 + s12*a2)^2

> As well, what would be the equivalent expression for the following
> example?

Pa(R0) = fPa + rPa + 2*SQRT(fPa*rPa)cos(GA)

Note the 180 degree phase difference between the two
examples. Why that is so is explained below.

> +-------+-------------+----------------------+
> | | |

If by "completely different", you mean 180 degrees different,
you are absolutely correct. The 1/2WL short-circuit and open-
circuit results are reversed when going from a voltage source
to a current source.

> Why is it not the same expression as previous since the conditions
> on the line are the same?

We are dealing with interference patterns between the forward wave and the reflected wave. In the voltage source example, the forward wave and reflected wave are flowing in opposite directions through the resistor. In the current source example, the forward wave and reflected wave are flowing in the same direction through the resistor. That results in a 180 degree difference in the cosine term above. I believe all your other excellent questions are answered above.

What you seem to be missing is that Richard H. said
absolutely nothing about radiated *power*. The radiation
pattern is certainly a function of loop area.

Does anyone know the size of the dish antenna they will be using? 10m?

From: http://www.thepoles.com/news.php?id=16912

12:08 pm EST Jan 15, 2008
(ThePles.com) A 17-member Chinese expedition team Saturday reached Dome A, Xinhua reports. The scientists reached the dome with an elevation of 4,093 meters at 11:45 a.m. local time (0645 GMT) after a 21 day journey.

Dome A or Dome Argus is an Antarctican plateau located 1200 kilometres inland. Wikipedia reports that it is thought to be one of the coldest naturally occurring places on Earth, with temperatures believed to reach -90 °C.

While Mount Vinson (4,897m) on the southern part of the Sentinel Range is the highest altitude mark in Antarctica; Dome A is the highest ice feature, comprising a dome or eminence of 4,093 m elevation, located near the center of East Antarctica and approximately midway between the head of Lambert Glacier and the South Pole.

The perfect spot for an astronomical observatory

The team raised a flag and a memorial sculpture on the point. Expedition leader Sun Bo told Changcheng Station in Antarctica over satellite phone that all 17 members are well and will now select a location for an astronomical observatory and China's third Antarctic research station. The team will also spend 70 days on a scientific project dubbed "The Panda plan."

This is the second time that Chinese scientists have arrived at the dome after a similar climb on Jan. 18, 2005, the first ever by mankind, Xinhua reports.

The first attempt to reach the spot was in 1997; it failed after 300 kms and 13-days, however marking China's first Antarctic icecap expedition. Several more attempts followed, until on Jan. 18, 2005, 13 expedition members made the first ascent of Dome A.

The name "Dome Argus" was given by the Scott Polar Research Institute from Greek mythology; Argus built the ship in which Jason and the Argonauts traveled.

The coldest air temperature recorded at Dome A during 2005 was -82.5°C. The lowest air temperature (-89.2°C) at the surface of the earth was recorded in July 1983 at Vostok, which is almost 600 m lower in elevation than Dome A.

China currently has two stations in Antarctica. Changcheng Station, founded in February 1985, is located south of King George Island, and Zhongshan Station, built in February 1989, is located south of Prydz Bay on the Mirror Peninsula, east of the Larsemann Hills. The 17 researchers are part of China's 24th scientific expedition team to Antarctica.

China launched its first expedition to Antarctica in 1984, since when such expeditions have been conducted on an annual basis.

Roy,

Thanks for ANOTHER lesson. I have a SGC-230 tuner in the RV that I use to tune a wire when we go camping. I think the metal mounting brackets are isolated from the floating tuner chassis and that you have to use a grounding lug on the bottom. Never verified that since I have always used the ground lug anyway. I was thinking of adding ferrites to the input side of the tuner and then using it to tune a dipole fed with 450 ohm window line. Maybe I'll just stick with the longwire.

I noticed the guy who wrote that article mounted his tuner on an el cheapo cutting board, probably just for that reason.

Which, of course, illustrates the point that I believe Roy made in the article, that the load conditions (whether they are the result of something going on involving a transmission line, or just a lumped load) tell us nothing about what's going on inside a source, ideal or otherwise. For that, you MUST know the characteristics of the source itself, and for that you do NOT need to know anything about the load beyond the impedance it presents to the generator output terminals (possibly as a function of time, frequency, amplitude and other factors). For example, in the case of the signal generator on my bench when 100dB of attenuation is cranked in, the change in dissipation inside the generator versus load impedance is inconsequential: at least 99.999 percent of the generator's available RF output is dissipated in the attenuator when the load is matched (50 ohms). The additional maximum possible 0.001 percent increase depending on load would be difficult to detect: about 0.00004dB change. On the other hand, the change in dissipation inside my 450MHz transmitter versus load impedance is substantial, BUT bears no resemblance to either the current-source-with-shunt-resistor or the voltage-source-with-series-resistor model, for multiple reasons.

Cheers,
Tom

My SG-230 tuner manual says that is a no-no.
It says: "The coupler must be located *at the antenna*.
Never use a feed line or coaxial cable at the output
of the antenna coupler."

That's true, but Roy specified exactly what was inside his source
so we are free to analyze it based on his specifications.

Cecil,

Saw that and wondered about isolating the coax and DC power with the
ferrite and maybe changing the rules about doing that. Since you're a
whole lot sharper than I am on this stuff, what do you figure the
reason is for not tuning a balanced feeder with it? That would make
things soooooooooo much easier if it worked.

Thanks.

>My SG-230 tuner manual says that is a no-no.
>It says: "The coupler must be located *at the antenna*.
>Never use a feed line or coaxial cable at the output
>of the antenna coupler."

On the other hand, page 16 of the SGC-230 manual PDF specifically shows a balanced dipole, being fed through "balanced line feeders, 300-600 ohms, up to 40 feet".

The ladder line is shown as being connected to the antenna "hot" terminal, and to the case of the coupler.

The manual is quite clear about not using a coax feedline above the antenna, or having a feedline out to a longwire antenna which has more than a very small amount of capacitance to ground. The information shown on page 16 suggests that you may be able to bend this restriction if you're using a balanced feedline, although I suspect that you'll still want to make sure that you've got low capacitance between ground and the hot side of the line (keep the feedline well away from metal, and use high-quality feedthrough insulators).

I don't know about using a balun at the base of the feedline... this will (almost of necessity) require the use of a length of low-impedance feedline of some sort, and this could be exactly the sort of thing that prevents the SGC from matching the line properly. Using a choke on the coax-and-control side might work better, although this too seems to be something that SGC discourages.

I haven't been terribly happy with the SGC tuner I picked up (admittedly for cheap, at a ham swap-meet). It's an early-model SGC 230, and its tuning algorithm seems very finicky. In particular, it won't tune into any but the easiest loads when fed by my Kenwood TS-2000. I suspect that the reason is that the TS-2000's high-SWR foldback circuit is rather aggressive, and chops the power down to well under 10 watts anytime the rig sees an SWR of more than 2:1 or so. The fluctuating transmitter power seems to confuse the coupler's matching algorithm... no big surprise there. Seems to work better when fed from a simple TenTec Scout, which has a different high-SWR-protection mechanism that doesn't cause the power to flop around as much.

Anyhow... my impression is that the SGC tuners are best suited for
their original application - feeding a whip or longwire, whilst being
securely bolted and multiply-grounded to a Big Metal Vehicle Chassis.
They also seem to do OK feeding verticals over a big bed of radials.
I just don't think they're all that well suited to feeding balanced
antennas.

Steven Best's article does have an equation of similar form:

PFTOTAL = P1 + P2 + 2 * sqrt(P1) * sqrt(P2) * cosθ

Starting with superposition of two voltages, he derived an
equation based on powers for computing the total power.

So that made sense. But why would adding in the forward
power in the line be useful for computing the power in the
source resistor? And the answer: Pure happenstance. The
value of the source resistor is the same as the value
of the line impedance, so identical currents produce
identical powers.

Perhaps you could carry out the calculations for a slightly
different experiment. Use a 25 ohm source impedance and a
voltage oF 70.7 RMS.

Forward and reverse power for the short circuited load will
still be 100 W, but only 200 W will be dissipated in the
source resistor. It is not obvious to me how to compute the
interference term for this case.

I see that now. It works because you were effectively using
superposition to compute the voltage across the source resistor
and then converting this to power using the expression derived
by Steven Best.

But it was happenstance that the voltage across the resistor
was the same as the forward voltage on the line. A very misleading
coincidence.

Used the SGC feeding a longwire this past Field Day and it kicked butt over a dipole at 80' fed with a conventional balanced tuner under most conditions. Surprised the heck out of us.

BTW - Used a pneumatic (tennis ball) antenna launcher to put up those antennas and it sure made it a lot easier than previous years using other methods. WELL worth the time to build one of those! Always wanted to try a loop though.

I believe there are still a lot of unknowns about antenna theory and
propagation and that something may someday come along that EZNEC
cannot properly calculate and model. There are several hams who may
or may not be lurking about this group that have invented 'new'
antenna designs that cannot be properly modeled by EZNEC.
Unfortunately, for the ones I know about, the information is held so
secretly close to the inventors that their designs cannot be properly
compared to other antennas of known design to validate the inventors'
claims.

I have been a ham for 29.5 years now and for HF base, I have almost
exclusively operated from my own home-brew antennas. I learned a few
things over the years, rules of thumb so to speak. For Yagi antennas,
the longer the boom, the greater the gain, the shorter the boom, the
wider the beam width. For wire antennas, (within certain constraints)
the more wire, the more gain, the longer the antenna, the better the
gain, the shorter the antenna (shortened antenna) the narrower the
bandwidth. It is very hard to get a 1/16th wave antenna to work as
well as a decent 1/2 wave antenna for the same frequency. Most
importantly, any antenna (that won't destroy the radio) will
communicate given adequate propagation between the two points.

I don't use EZNEC. I haven't had the time set aside for studying that
and antenna theory long enough to make good use of the program. I have
tried, but it isn't capable of modeling the antenna design that I want
to experiment with,

I don't say this to discredit Roy, as, in all honesty, from the bottom of my heart, I acknowledge that by far he has greater intelligence in the antenna field than I hope to have. But, his software has certain limitations and he states at least some of the limitations in his user manual.

There are a number of professional antenna specialists here, some real, some wanna-be. Some of those professionals don't care for us amateurs being here asking questions anyone with a Masters degree in antenna science shouldn't have learned by their fifth or sixth year of study. Others are glad to help as long as we have shown to have made some effort to understand the basics of how an antenna works.

I have respect for both Roy and Cecil, even tho they are quite often at odds with each other, and I have respect for others here as well. In time you will know who you want to trust and who you don't want to hear from.

Good luck,
Buck

> voltage-source-with-series-resistor model, for multiple reasons.

Yes. In all the cases, you can replace the transmission line and load with any other combination of transmission line and load which present the same impedance to the source, and the source resistor dissipation will be exactly the same.

For example, look at the first entry, 50 + j0:

```
Zl fPa rPa Pa(tx) Pa(src) Pa(R0) Pa(Rl) frac R0 frac Rl
50 + j0 100 0 100 200 100 100 0.50 0.50
```

If we used a 100 ohm transmission line instead of a 50 ohm transmission line, we'd have

```
Zl fPa rPa Pa(tx) Pa(src) Pa(R0) Pa(Rl) frac R0 frac Rl
50 + j0 112.5 12.5 100 200 100 100 0.50 0.50
```

There's no change in source or load dissipation even though the forward and reverse powers in the transmission line are different. If we do away with the transmission line altogether and connect the load directly to the source resistor, completely eliminating traveling waves, the result is exactly the same.

A literally infinite number of other examples, using various line impedances, load resistances, and line lengths, can be created. You'll

find that the *only* factor (other than source voltage and source resistance value) which determines source resistor dissipation is the impedance which it sees - regardless of how that impedance is created. It has nothing to do with constructive or destructive interference, traveling waves of voltage, current, or power, or anything else happening on the line, or even if there is a line at all. And the exact amount of source resistor dissipation can be immediately calculated by analyzing a simple circuit of three components: the voltage source, the source resistance, and the impedance seen by the source resistance. No other information is required.

Hi Buck

My comments related to computer modeling are directed to the validity of the EZNEC results. I want to support the fact that it works. There is no question that there may be some concepts that EZNEC cant deal with. My thoughts about EZNEC relate to its ability to give good answers to questions with which it is intended to be used. I consider the EZNEC program to be quite accurate for the VHF antenna concepts I work with. I worked fairly consistently for a couple years on an antenna design concept that was written up in the Feb 2008 QST and consider EZNEC to be responsible for my being able to better understand the concept. I would certainly never be without the program, now that I have used it.

2443. Horizontal loop antenna - Dual Wire

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-20 03:55:20 UTC
From: Buck <usenet01@lumpuckeroo.com>
Message-ID: <i09nr3p2n2d3d0kqrbgv35kfan37qmdlqg@4ax.com>
Source record: 27865

I seem to remember an article about someone taking a full-wave horizontal loop antenna and making two loops (or was it a half-wave loop?). The second loop caused the antenna to match 50 ohms so it could be fed with coax and (I think) it operated multiple bands. Anyone remember this article and know where it might be?

Thanks
Buck

I was so sharp, I called SGC. :-) They said if the
transmission line accidentally opened up, the SG-230
could develop 30,000 volts at its output. If it was
mounted in an attic, for instance, it could burn the
house down. I think they are worried about being sued.
Moral: If you decide to use transmission line on the
output, put it in a location that will not matter if
it catches on fire.

Roy Lewallen wrote:
> No other information is required.

No other information is required if, as you assert, you don't care where the power goes. You said: "I personally don't have a compulsion to understand where this power 'goes'." That's perfectly acceptable, but don't turn around and present yourself as an expert on "where the power goes". Please choose either not to care or to engage in a technical discussion of where the power goes. It is not fair play for you to try to have it both ways.

If it is applied properly, the power-interference equation tells us exactly where the power goes so your following statement is false: "While the nature of the voltage and current waves when encountering an impedance discontinuity is well understood, we're lacking a model of what happens to this 'reverse power' we've calculated."

We are NOT lacking a model of what happens to the "reverse power". You have just chosen not to understand the model and are trying to use your guru status to belittle and discredit anyone attempting to use that model. Are you afraid it might turn out to be valid?

The derivation proves the equation to be valid.
The redundancy inside a transmission line of Z0 characteristic
impedance means we don't have to deal with voltages at all if
we know the length of the transmission line and the reflection
coefficient of the load. Pfor = Vfor^2/Z0 Pref = Vref^2/Z0

> Perhaps you could carry out the calculations for a slightly
> different experiment. Use a 25 ohm source impedance and a
> voltage oF 70.7 RMS.

Note you are cutting the source voltage and source resistance
in half while keeping the rest of the network the same. The
forward power cannot remain at 100w.

> Forward and reverse power for the short circuited load will
> still be 100 W, but only 200 W will be dissipated in the
> source resistor. It is not obvious to me how to compute the
> interference term for this case.

Nope, forward and reverse power will not still be 100w.
Forward and reverse power will be 50w. It will be
44.44w + 4.94w + 0.549w + 0.06w + ... = 50 watts
The source is now exhibiting a power reflection coefficient
of 0.3333^2 = 0.1111 so there is a multiple reflection
transient state before reaching steady-state.

50w + 50w + 2*SQRT(50w*50w) = 200 watts

Could be... I was using a PDF copy of the manual I downloaded from the SGC website. Possibly the newer versions of their couplers have more flexibility in their tuning algorithm?

Hi Buck,

It is a small tuned loop (less than a tenth wave) with a smaller loop
(about a third to a fifth in size of the first loop) inside it.

Not much else to say except that polarity is vertical/horizontal when
the loops are in the horizontal/vertical plane. Make every effort to
build low Ohmic connections and elements. The capacitor will have to
stand off a high voltage (and many caps suffer from ESR).

Roy Lewallen wrote:
"I don`t see anywhere in the response which explains how "radiation is a function of loop area" and why increasing the loop circumference would be advantageous."

Didn`t want to bore with details. Terman knows all and tells all. His loop antenna story begins on page 907 of his 1955 opus:
"The radiation resistance of a loop antenna is less the smaller the loop area. For the radiation resistance to be large enough to give good antenna efficiency, it is necessary that the loop perimeter be of the order of a wavelength. This introduces a difficulty, since when the perimeter approaches or exceeds a half wavelength, then the loop current in Fig. 23-40 will not be constant, nor will its phase nnecessarily be the same in different parts of the loop. The prectical solution is to build up the loop in such a way that the perimeter consists of resonant antennas so arranged that the current everywhere in the loop perimeter flows in the same direction around the loop. A variety of practical physical arrangements for achieving this result have been devised, three examples of which are illustrated in Fig. 23-41."

Yet another elegant phase inverter from Kraus as applied to a colinear dipole appears on Cecil`s webpages.

Best regards, Richard Harrison, KB5WZI

Roy Lewallen wrote:
"Perhaps you build antennas for radiation resistance, but I think most people build them to maximize radiation in some particular direction.."

You must have some radiation resistance or you have no signal, but not all antennas are highly directional.

Page 8-10 of the 20th edition of the ARRL Antenna Book has (Eq 5):
Efficiency = radiation resistance / radiation resistance + loss resistance

Zero radiation resistance = zero efficiency.

The antenna article I was referring to is either full size or 1/2 size
horizontal loop and he used window line (twin-lead) wire for the loop
crossing the connection of the coax so that the wire made a continuous
loop twice going from the center conductor to the shield (he may have
used a balun, but you get the idea). This was a large loop running
around his yard.

Thanks, tho.

Not quite, since the angle 'theta' is the angle between the voltages,
is it not?

> The source is now exhibiting a power reflection coefficient
> of 0.3333^2 = 0.1111 so there is a multiple reflection
> transient state before reaching steady-state.

I suggest that you forgot to use Steven Best's equation when
you added the powers. Consider just the first re-reflection
where 4.94 is added to 44.4.

Pftotal = 44.444444 + 4.938272 + 2 * sqrt(44.444444) * sqrt(4.938272)
* cos(0)
= 49.382716 + 9.599615
= 79.01 W

To verify, let us consider the voltages:

Original Vf is 66.666666 V (peak)
First re-reflection is -66.666666 V * -0.3333333 -> 22.222222 V (peak)
giving a new Vf of 88.888888 V (peak)
which is 79.01 W into 50 ohms.

It does, indeed, converge to 100 W forward but you have to use the
proper equations when summing the powers of superposed voltages.
You can not just add them.

So forward and reverse powers each converge to 100 W and 200 W is
dissipated in the source resistor, which suggests that your
equation for computing dissipation in the source resistor is
incorrect.

To take the tedium out of these calculation you might like the
Excel spreadsheet at

You're right that low radiation resistance makes it hard to attain high efficiency. You want radiation resistance to be significantly higher than loss resistance.

But ohmic losses usually aren't that bad in large dipoles and loops. EZNEC or other modeling progarms can tell you how much you gain by going up in wire size. For common geometries and wire sizes, the difference will be a small fraction of a decibel.

For small ("magnetic") loops on the other hand, efficiency is very much an issue, and you want to push the radiation resistance as high as you can, and ohmic losses as low as you can. (Increasing the size of the loop is the easiest way to increase radiation resistance, but presumably there's a reason that you'er using a small loop in the first place.

Define equilibrium. As far as I can tell, you seem to infer
that being in "equilibrium", means that it is resonant.
I hate to break it to you, but being resonant is no sure
road to efficiency as a radiator of RF.
How many hundreds of feet of wound 22 gauge wire does this
device contain?
Seems to me, if I ponder all the laws of the "masters",
you have reinvented an air cooled dummy load that probably
won't handle too much power before it becomes so hot as
to melt whatever is close to it.
Maybe I suggest a Heathkit "Cantenna" as a better oil
cooled substitute that can be ground mounted for ease of
use. You can blast it with your 8877 for short periods
of time, and I doubt it will melt any plastic that is lying
next to it. Requires no tower, and no need for garbage can
lids.
According to the law of Art, it is in equilibrium, and
should satisfy all the requirements of the masters,
whoever they may be, and wherever they may lie.

Hi Mark,

Perhaps for Arthur's twist on an old concept, but for his argument's sake, he need only lift off the shield for his finals with their Plate Tank circuit to achieve "equilibrium." And how effective does this full wave radiator perform? Hertz walked away from it 120 years ago when everyone thought 160M was useless SHF.

I would point out this observation of the Plate Tank is not original to me. It was pointed out to Arthur, in eham (a forum of his choice for comity and gentlemen's conversation) where he flipped the fellow off and never looked back.

Yes. That is how government and much of industry which work on fiscal year budgets work. Timing is predictable for expenditures on less prudent projects too. Carefully hoarded approved budgets are suddenly excesses at year end. They must be spent or returned to the treasury. Return means a reduction of influence and power.

> is it not?

That's part of the redundancy I was talking about. If one
calculates the voltage reflection coefficient at the load
and knows the length of the transmission line, one knows
the angle between those voltages without actually calculating
any voltages. For a Z0-matched system, one only needs to
know the forward and reflected powers in order to do
a complete analysis. No other information is required.

> I am pretty sure that it is 100 W. See more below.

Good grief, you are right. I wrote that posting and made
a sophomoric mistake after a night out on the town. I
should have waited until after my first cup of coffee
this morning. Mea culpa.

> It does, indeed, converge to 100 W forward but you have to use the

You're right - 20 lashes for me. Some day I will learn not
to post anything while my left brain is in a pickled state.

> So forward and reverse powers each converge to 100 W and 200 W is
> dissipated in the source resistor, which suggests that your
> equation for computing dissipation in the source resistor is
> incorrect.

It happened to be correct in the earlier example because
the ratio Rs/Z0 = 1.0, so the equation was correct
for those conditions. Rs/Z0 needs to be included when
the source resistor and the Z0 of the feedline are different.
Now that I've had my first cup of coffee this morning, let's
develop the general case equation. Note that we will converge
on the equation that I posted earlier.

>> 50w + 50w + 2*SQRT(50w*50w) = 200 watts

The interference is not between the forward wave and reflected wave on the transmission line. The interference is actually between the forward wave and the reflected wave inside the source resistor where the magnitudes can be different from the magnitudes on the transmission line.

Note that the forward RMS current is the same magnitude at every point in the network and the reflected RMS current is the same magnitude at every point in the network.

Considering the forward wave and reflected wave separately, where Rs is the source resistance:

If only the forward wave existed, the dissipation in the source resistor would be Rs/Z0 = 1/2 of the forward power, i.e. (Ifor^2*Z0)(Rs/Z0) = Ifor^2*Rs = 50 watts.

If only the reflected wave existed, the dissipation in the source resistor would be 1/2 of the reflected power, i.e. (Iref^2*Z0)(Rs/Z0) = Iref^2*Rs = 50 watts.

We can ascertain from the length of the feedline and from the Gamma angle at the load that the cos(A) is 1.0
This is rather obvious since we know the source "sees" a load of zero ohms.

Now simply superpose the forward wave and reflected wave and we arrive at the equation I posted last night which I knew had to be correct (even in my pickled state).

P(Rs) = 50w + 50w + 2*SQRT(50w*50w) = 200 watts

For the general equation: P1=Pfor(Rs/Z0), P2=Pref(Rs/Z0)

P(Rs) = P1 + P2 + 2[SQRT(P1*P2)]cos(A)

And of course, the same thing can be done using voltages which will yield identical results. What some posters here don't seem to realize are the following concepts from my energy analysis article at:

http://www.w5dxp.com/energy.htm

Given any two superposed coherent voltages, V1 and V2, with a phase angle, A, between them:

If (0 <= A < 90) then there exists constructive interference between V1 and V2, i.e. cos(A) is a positive value.

If A = 90 deg, then cos(A) = 0, and there is no destructive/constructive interference between V1 and V2, i.e. cos(A) = 0

If (90 < A <= 180) then there exists destructive interference between V1 and V2, i.e. cos(A) is a

negative value.

Dr. Best's article didn't even mention interference and
indeed, on this newsgroup, he denied interference even
exists as pertained to his QEX article.

The failure to recognize interference between two coherent
voltages is the crux of the problem.

> antennas.

It's the decay of newsgroups. People decide a given newsgroup is their
hangout, rather than a place to dicuss the topic the newsgroup was created
for. So instead of going to a newsgroup to discuss the off topic things
where they are on topic, they decide they should share the off topic stuff
with their "buddies" in the favorite newsgroup.

I've seen people come into a newsgroup, and jump into that hangout mentality
without ever really participating in the newsgroup for its intended purpose.
They fit in because they just have to emulate the people who are using
it as a hangout.

Puttiung "OT" in the subject header is just a way of legitimizing it all,
they figure it hey are polite and label the off topic posts, then it's okay.
It completely sidesteps the issue of why the off topic junk is there in
the first place.

I still read newsgroups I've read for over a decade that barely have
any traffic in them.

But I keep leaving newsgroups that I've been reading and posting to
for as long, as they turn into hangouts for such people. I don't want
to wade through the junk.

The people who see the newsgroup as their hangout don't see an issue
because they are perfectly happy to talk about off-topic things.

IN reality, they are extremely selfish, since they are only thinking
of their own happiness, and not the state of the newsgroup. They
think because they are the most frequent posters that that gives
them say. Meanwhile, the newsgroup loses the people who stick around
and post when they actually have something valid to say, because they
aren't interested in the off topic junk (at least not when it's off topic,
they are likely the ones who go to multiple newsgroups to fulfill their
need to discuss multiple topics). Go far enough, and the only posters
are the ones who use it as a hangout, and pretty much none of what they

say is on-topic. Maybe more important, if their only interest is in talking to a handful of other "regulars" then they might as well move to a private space, where they can discuss anything they want without any interlopers.

And the joke is that people will say "but we don't care, we want to do this". All of the newsgroups I've left because of this inane behaviour, I was there before these people came along and decided to turn the newsgroup into their own hangout.

These same smug people are all so quick to go after spam, and other "interlopers" but they don't realize that they are the ones killing the newsgroups.

Art wrote:
"It is not physical size that is important with respect to a dish it is the wavelength between two objects that counts. A simple helix antenna can use a reflector in place of a ground plane not used as an optical ray reflector."

Yes, but, size matters even when you are told it doesn`t. A dish usually makes the path length equal between its frontal plane and focal point for all rays by the parabolic curvature of its reflector. Everything stays in phase by virtue of traveling the same distance through the same medium. The bigger the dish, the higher the gain.

On the helix antenna invented by Kraus, Terman writes on page 909 of his 1955 opus:
"The directive gain is appreciable, a six-turn helix having a diameter of 0.30 lambda sith a spacing of 0.30 lambda between turns developing a gain of 45 when provided with a reflecting screen at the input and that is normal to the helix axis. A helical antenna is relatively broadband in its characteristics."

>I still read newsgroups I've read for over a decade that barely have >any traffic in them.

Hi Michael,

It wasn't until your post, that I found any reason to participate in this Off Topic thread. It consists largely of griping and issues unrelated to antennas, but I've no problem with that if you want to hang out here and offer comments.

I do, however, enjoy analysis to topics whatever their stripe and this opportunity presented itself. When speaking about newsgroups that barely have any traffic in them, I would count rec.radio.amateur.moderated. I find it amusing that like the weather a lot of talk is offered, but no one really does anything about it.

I only occasionally venture to gather the latest 200 headings from rec.radio.amateur.moderated and I find nothing there that is particularly interesting. One of the frequent posters is(are) the moderator(s). Mobile Power connector talk overwhelms that of antennas 19:1. This would seem to be an intellectual entropy institutionalized by moderation and has offered the world a rec.radio.amateur.moderated.off-topic sink (but that hasn't worked very well either). Thus by the balance of moderation vs. non-moderation offered, both venue's decline in participation is unbiased, but moderation appears to be a non-starter, lacking any ignition. As for instance in the last 200 headers, they reach back before Thanksgiving, and are notably sparse for this month (perhaps the server lost interest too). In comparison, my reader currently holds 5500 headers (not counting junk posts) for roughly the same period. Clearly posters voting with their "Send Message Now" button have announced what works best.

From the evidence of those who complain about the lack of comity, discipline to topic, and the rest, I find none of them having migrated to rec.radio.amateur.moderated. Even more so, from those who complain about some posters here, I find those who've been complained OF at rec.radio.amateur.moderated.

Interesting contradiction in expectations, inversion of behaviors, and disconnected mandates.

I got the info w.r.t PUSC permutation from http://ieee802.org/16 :-

I find that the PUSC permutation has
1) Outer Permutation and
2) Inner Permutation
Further, These permutations reduce interference .
Cross-interference between neighboring cells is reduced between
neighbouring cells,
w.r.t subchannels.

But, why have they opted for this renumbering scheme to introduce
permutation ?

Thx in advans,
Karthik Balaguru

Source record: 27801

Keith Dysart wrote:
> So forward and reverse powers each converge to 100 W and 200 W is
> dissipated in the source resistor, which suggests that your
> equation for computing dissipation in the source resistor is
> incorrect.

I remembered what I did when I used that equation. It is
the same technique that Dr. Best used in his article. If
we add 1WL of 25 ohm line to the example, we haven't
changed any steady-state conditions but we have made the
example a lot easier to understand.

```
Rs 50w--> 100w-->
+--/\/\/--+------------------------+------------+
| 25 ohm <--50w <--100w |
| |
Vs 1WL 1/2WL |Short
70.7v 25 ohm 50 ohm |
| |
+---------+------------------------+------------+
```

Now the forward power at the source terminals is 50w and
the reflected power at the source terminals is 50w. So the
ratio of Rs/Z0 at the source terminals is 1.0. Therefore:

P(Rs) = 50w + 50w + 2*SQRT(50w*50w) = 200w

> To take the tedium out of these calculation you might like the
> Excel spreadsheet at

I think that almost all cellphone spam is based on simply dialing
numbers in sequence on an exchange known to belong to cellphones,
rather than being directed to you specifically.

Since it's already illegal to use machine dialers to call cellphones,
adding your number to a don't call list certainly won't mean much to
the caller.

On the other hand, I've had a Verizon account with two lines for about
10 years, and have been carrying a T-Mobile pre-paid phone for about a
year and have never, ever received any unwanted phone calls or text
messages.

Now that's a tall order! The taps are the hard part since that depends
on your construction.

But then, winding a helical for 80M is not going to be fun, either. If
memory serves, I think you need a half wavelength of wire wrapped
around a pole.

Eric

Seems to me the wind loading is going to be
a severe problem. Let's say it is 8 feet long.
At 2 turns per inch, it would need to be about
3 inches in diameter. That's about 200+ square
inches of wind loading. It will probably require
a guyed fiberglass pipe as a coil form. I calculate
about 150 feet of wire is needed for the above design.

What he wants to build is what outbacker sells.
Has taps with banana plugs to change bands.
I don't know of any plans to build one.
It wouldn't be that big a deal though. A bit
tedious finding the tap points, but it can be done.
You could calculate the various points to get in
the ballpark, and then clip to, or probe the wires
to fine tune the tap.
I'd probably start on the lowest band and go up to
the highest freq it will tune with whatever length
stinger whip it is using.
My plastic bug catchers are about the same thing,
but using a single lumped coil, vs the thinner helical
winding. It's best to concentrate the windings at the
top of the glass whip to improve current distribution.
Using an even space winding along the whole stick
is not quite as good in most cases.
MK

I too have been called by telemarketers on my cell phone - and the number has been listed at the federal do-not-call site since the 3rd day I had the number years 2+ years ago. The FCC and the FTC are completely ineffective. The only way to stop these jerks is to report the violations to your state's (and their state's - if they're somewhere else) attorney general's office. I've had to do that twice so far (for 2 places that each called 10+ times).

I am surprised to have read positive responses in this thread--the ones describing a lack of such calls. Perhaps I just live life wrong, but I was getting tons of these--on a personal ATT line, even on a business line--and, both on MetroPCS and Verizon cellphones I have--even a clearwire wireless internet connection employing Vonage as the local/long-distance carrier.

Listing my numbers in the national no-call database has finally brought these to a halt; Well, almost, now and then a "spam-phoner" breaks through--even my just inquiring who is calling on the other end brings a prompt hangup from the other end, go figure--for a bit I even went paranoid and wondered if it was the CIA or FBI were exhibiting such strange behavior and tapping my phones! <GRIN>

Anyway, I think the national no-call list works, but takes about a week to go into effect (if my experience can serve as an example.)

But, late at night--when I can't sleep--I still worry about those calls which sneak through ... ??? :-|

P.S.

You wouldn't consider a construction post on a "how to" post on building a back scratcher out of an old element broken off, by the wind, from a VHF yagi, would you? I mean, I can certainly understand your opposition to "frivolous" posts of little worth, but certainly you have boundaries on your objections--I mean, don't you? <ROFLOL!>

Two Saturdays ago I was on a road trip and used
9 litres/100km. How can anyone argue that the fuel
consumption is never equal to the day of the month?
Numerical coincidences can be much fun.

But you will like the generator below even better.
The power dissipated in the generator resistors is
always equal to 50 + Pref, regardless of the load
and line length, thereby always accounting for Pref.

Pfor=50w-->
+--/\/\/---+----------------+------------------+
| 100 ohm | <--Pref |
| | 100 ohm |
| +--/\/\/--+ any length |
| ^ | 50 ohm line any load
Vs Is | |
100v RMS 1A RMS | |
| | | |
+----------+---------+------+------------------+
The generator output impedance is 50 ohms.

Dissipation in the generator resistors is always
50 Watts plus Pref.
With a shorted or open load, the power dissipation
in the generator is 100 W.

Numerical coincidence as proof that Pref is always
dissipated in the generator. :-)

On a more serious note, how would you analyze this
generator using reflected power and constructive
and destructive interference?

...Keith

Keith Dysart wrote:
> Numerical coincidence as proof that Pref is always
> dissipated in the generator. :-)

It's no coincidence. The special case example was carefully selected to make the angle 'A' between the forward and reflected waves equal to 90 degrees. Since cos(A) exists in the interference term and cos(90) = 0, it makes the interference term equal to zero.

When there is no interference at the source resistor, 100% of the reflected power is *always* dissipated in the source resistor. This is a chosen special case condition, NOT a coincidence. In the absence of interference, there is simply no other place for the reflected energy to go, i.e. it cannot be redistributed back toward the load.

There are any number of special cases that will cause the forward wave and reflected wave to be 90 degrees out of phase at the source resistor. One of Roy's cases was just such a case - 1/2WL of 50 ohm feedline with a 0 +/- j50 ohm load.

For any length feedline, there exists a load that will cause the reflected wave to be 90 degrees out of phase with the forward wave at the source resistor. For any of those infinite number of cases, the reflected energy will be dissipated in the source resistor.

> On a more serious note, how would you analyze this
> generator using reflected power and constructive
> and destructive interference?

Without analyzing it, based on our previous discussion of voltage sources and current sources, I would say that any constructive interference in the voltage source is offset by an equal magnitude of destructive interference in the current source and vice versa, i.e. the net interference inside the source is always zero.

Any TV channel can be used for analog or digital.
As of early 2009, all channels will be digital.

All of the TV frequencies fall into one of three ranges: VHF low-band (traditionally channels 2 - 6), VHF high band (channels 7 - 13), and UHF (channels 14 on up).

During the big digital-TV transition, the upper end of the UHF frequency range (700-800 MHz) is going away entirely. It's being auctioned off or allocated to commercial and public-safety interests.

During the transition period, the full-power TV stations have each been allocated a second channel in the remaining portion of the UHF frequency band, which they've been using for their ATSC (digital-TV) signals... these are on UHF channels which had not previously been used in the station's service area. The stations have continued to transmit NTSC analog on their original frequencies.

It's important to understand that with digital TV, the "station number" displayed on the TV, and to which you tune, doesn't necessarily correspond to the actual RF frequency.

During the final switchover, each station will either:

- Drop its old NTSC frequency entirely, and move its full-power transmission to its current (transition) ATSC frequency, or

- Stop using its ATSC transition frequency, and switch its current NTSC transmitter over to ATSC digital, or

- Drop its old NTSC frequency, and start transmitting ATSC digital on a newly-allocated frequency.

My impression is that most of the stations now on channels 14 on up (UHF) will be doing the second of these. Most of the stations now on VHF will do the first of these - they'll give up their VHF frequency and move to UHF.

There *are* a few stations which will keep using their VHF frequencies (channels 2 - 13) and just switch them over to full-power digital operation. Most of these are in the VHF highband (7-13), but there are a small handful in the lowband (2-6) which will stay there.

In many areas of the country, a good UHF-only antenna is all you will need for digital TV, after The Big Day. This is fortunate for the

many people who have bought "digital TV" antennas - most of these are UHF-only.

In urban areas of the country, quite a few people will need antennas which handle both UHF, and the highband part of the VHF spectrum.

In a very few urban areas, people will need antennas with full-frequency TV-band coverage (VHF low, VHF high, and UHF) in order to get all of the channels.

2508. Sierpinski monopole/dipole carpet antenna (SC) for HF

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-23 02:34:10 UTC
From: AI4QJ <nospam@hotmail.com>
Message-ID: <47bf8620$0$4936$4c368faf@roadrunner.com>
Source record: 27829

This antenna is multiband but most of the literature I have seen talks to experimentation in the UHF bands. It seems to have very high gain and actually acts much like a log periodic. Has anyone experimented with this concept in the HF bands. It is sometimes considered a "fractal" antenna (more by coincidence then by intent I suppose) but it's properties on paper seem to be ideal for operation in the ham bands. I have a nice sized attic and its compact design may make it an ideal attic antenna at least up to 40m. Can one really expect 10dB gain, 25% bandwidths and VSWRs at multiples of lambda at 2X, as studies in the UHF regions show?

http://www.co.it.pt/conftele2007/assets/papers/antennas/paper_2.pdf

I vaguely remember some "Communications Quarterly"
articles on fractal antennas around 1990+. A CD-ROM
of back issues is available from the ARRL.

I was looking at this more as a bowtie antenna with internal embedded bowtie antennas (making it multiband). I wasn't looking at this specifically as a "fractal antenna" since there is no need to go into mandelbrot math. It is called sierpinski simply due to the inventor of the triangle within a triangle pattern ad infinatum which was published in 1905 (or something like that), way before fractal math was invented. Some people do consider it also to be a "fractal", I know. It does appear that telecom companies have been taking notice of the sierpinski carpet design for cell phones....perhaps using the same design on HF is relatively unexplored. It looks promising for a compact HF design.

It's easy to lose sight of what's important when you get bogged down in numerical coincidences and the like. To me, some things are clearly important with respect to analyzing such systems:

1. If a generator is linear and matched to a line (Zgen = Zline, not Zgen* = Zline), then no matter where a "reverse" signal comes from, that signal does not reflect at the source:line junction. The "reverse" signal can come from a reflection at a load, from another generator at the other end of the line, from something feed in through a coupler, from an electric eel biting the line--it doesn't matter. There is no need for an analysis involving "constructive" or "destructive" interference.

1a. Just because a "reverse" signal on the line does not reflect at the generator:line junction, that does NOT mean that additional power is dissipated inside the source.

2. You MUST have an accurate model of the inside of the source to know how it will respond to some particular load and to signals that impinge on its output port. With respect to figuring out what goes on inside the source and what power may or may not be dissipate there, there is NO advantage to knowing how the load or signals got there.

3. To correctly analyze conditions on a line that's fed only from one end, with a load on the other end, there is NO NEED OR ADVANTAGE to know what goes on inside the generator (beyond knowing the power it delivers to that effective load, perhaps).

3a. There may be some advantage in knowing the source impedance of a generator (or transmitter) in calculating the power delivered to a load at the source's output port, but there is no advantage to knowing it if you want to determine the standing wave ratio or reflection coefficient on the line, or what net impedance that line+load presents

to the source; that is all determined solely by the line and the load.

The stuff about constructive/destructive interference with respect to figuring out what happens inside a source is, to me, just so much dancing on the head of pins. Welcome to dance if you so wish, but I'd just as soon sit that one out.

Cheers,
Tom

Apparently it can be run as a monopole or dipole. I wonder how they achieve
the stated 50 ohm impedance match? Or perhaps that is the impedance it
happens to be a low VSWR frequencies.

Is it a coincidence when one amp flows through a one ohm
resistor with one volt across it and dissipates one watt?
No, it is the laws of physics in action. The fact that
everything is a unity magnitude is because of the particular
values chosen for the example.

My example was NOT coincidence. I deliberately chose values
that would cause the forward wave and reflected wave to be
90 degrees out of phase at the source resistor. Under those
conditions, there is no interference present and all of the
reflected energy is dissipated in the source resistor. There
are an infinity of such examples and it is true for both
voltage sources and current sources.

The fact that there is even one example discredits the assertion
that reflected energy is *never* dissipated in the source.

An interference analysis reveals exactly where all the energy is
going and that's what this discussion is all about. It may not
matter to you but it obviously matters to Keith and me.

> 1a. Just because a "reverse" signal on the line does not reflect at
> the generator:line junction, that does NOT mean that additional power
> is dissipated inside the source.

That's true. If total destructive interference exists at the
source resistor, then all of the reflected energy is redistributed
back toward the load. For the simple sources we have been using,
predicting how much reflected energy is dissipated in the source
resistor is a piece of cake.

I took Roy's chart and without calculating a single voltage or
current, not only matched Roy's correct results but I uncovered

an error he had made. That's a pretty good track record considering
that Roy's data went unchallenged for many years.

> 2. You MUST have an accurate model of the inside of the source to

We are discussing single-source, single transmission line, single
mismatched load systems. Where the energy components come from is
obvious.

> 3. To correctly analyze conditions on a line that's fed only from one
> end, with a load on the other end, there is NO NEED OR ADVANTAGE to

This discussion is all about what is going on inside the source.
If you don't care to engage in that discussion, please feel free
not to.

> 3a. There may be some advantage in knowing the source impedance of a

The argument about what happens inside a source is about 20 years
old now and is still raging. I'm simply trying to contribute
something to that argument.

> The stuff about constructive/destructive interference with respect to
> figuring out what happens inside a source is, to me, just so much
> dancing on the head of pins. Welcome to dance if you so wish, but I'd
> just as soon sit that one out.

That's your opinion and that's OK. If you choose not to attempt
to understand interference, you will forever remain ignorant of
its usefulness as an analysis tool. For the simple examples presented
so far, how much reflected power is dissipated in the source
resistor has been accurately predicted for all examples.

The interference phenomenon is well understood in the field of
optical physics and is a very useful tool in that field. The
principles are the same for RF waves. Why not use the tool?
Incidentally, optical physicists are NOT dancing on the head
of a pin when they calculate the irradiance of the bright rings
and dark rings.

Hi Dan,

All depends on what you mean by "promising."

Fractal antennas, historically, have "promised" a lot, and in and of themselves have proven to be no more _____ (fill in the blank with any presumed benefit) than a random wire pattern.

Fractal antennas, historically, have never broken out of the pack. 10-15 years is long enough for the votes to have been cast, counted, and taken to the Supreme Court for the judicial thumb on the scales. There's a good reason why you don't see them advertised (and only "mentioned") = underwhelming.

Dear AI4QJ: Work through the numbers found in the paper. Each full-size
triangle has a height and width of about 0.26 WL at the lower resonant
frequency. Assume a balanced pair of full-size triangles and one has the
length of a 0.5 WL dipole. The latter is much more easy to tune!

The only positive thing about this antenna is the possibility of having a
second resonance at about two times the lower resonance.

A somewhat fat dipole that is not necessarily resonant at any amateur radio
frequency (but fits your space) fed by a tuner seems to be the ticket.
When we built our house, I ran a wire just under the ridge line as a back-up
antenna.

I dunno. Probably weight, and being able to avoid the
usual industrial strength mount required for the heavy
antennas.
But using a helical stick is no sure route to disaster.
I've used a few that were so close to bugcatchers in
performance you could hardly tell the difference on the
air.
But... they were modified sticks, and not the usual you
buy at a store.
IE: if I want a 40m stick, I don't use a regular 40m version.
I use a 20m version and a longer stinger. I also try
to use one that has the bulk of the windings near the
top to improve current distribution. The helical whips
act the same as a lumped coil antenna in this regard.
You will have a more linear current distribution if you
wind most of the coil near the top, and then use a pretty
long stinger above it.
Being that in most cases ground losses are higher than
coil losses, often the ground loss swamps the coil
loss, and you end up not seeing as large a difference
as you would expect.
I often see the same comparing larger lumped coils.
IE: a 3 inch vs a 6 inch diameter coil..
In theory the 6 inch should be quite a bit better, being
less turns are needed, but often in the real world the
difference is hardly noticeable being the ground loss
is pretty high.
The worst helical whips are the ones that use no or a
very short stinger whip. If you want to use a thin helical
whip, you *must* use a pretty long stinger above the
glass whip if you want any kind of decent performance.
The 20m stick I used on 40m was very stout. But it
was 6 ft of 20m glass whip with the windings at the top,
and 5 ft of stinger. 11 ft total.

Made the car look like one of those RC cars... :/
But that antenna eventually became my present
lumped coil "plastic bugcatcher.

It can be represented as a point within the unity reflection
coefficient circle on a Smith chart...

Seriously, it depends on SO many factors you haven't specified that
it's not realistic to expect a single answer. How high above what
kind of ground? How many turns, spaced how? What diameter is the
helix? Is it stretched in a straight line, or bent? ...

Cheers,
Tom

If you really want a great performing mobile, and you want to build
it yourself, you might consider this:

http://faq.1and1.com/web_space__access/protected_directories/3.html

Scroll down to the bottom and click on "80-10M mobile vertical".
The PDF that comes up will contain all the info you need to build
yourself an efficient, and tunable, 80-10M bug-catcher type mobile
antenna.

I built myself a custom version of this for my motorhome and it is
outstanding.

Thanks Rich,

As I was saying before, I do not really think it is necessary to go along
the "fractal" path when analyzing the sierpnski. One could also consider a
dipole as an extremely simple fractal
but we do not need mandelbrot math to deal with it. Fractal afficianodos
seem to latch onto sierpinski as the 'first' fractal, because it is probably
the only 'fractal' antenna that works reasonably well.

Witness the common bowtie design of many UHF TV antennas. Currently, I have
reviewed a Yatpak simulation of a sierpinski carpet and it looks very good.
This one is going to be fun.

Hi Dan,

The way to judge fractals is by application, not by antenna
comparison. Yes, this may seem to be a contradiction in terms (all
applications have antennas which thus are compared).

If you pick a sierpinski for one application, it may well perform
better there than others, it may well not - if 2dB difference is of
any consequence.

There are MANY characteristics of comparison. Sometimes the
conventional design wins, sometimes the fractal. It also depends on
how you price your time in a COST/BENEFIT ratio. Implementation is a
bitch and if you are going to put in the effort for the fractal, you
might easily find an antenna design that is 70 years old doing better
for less effort. Thus, it means you may be comparing the wrong
antenna designs (and why application should drive choice).

If you simply want to experiment, then there are some really
convoluted designs few consider.

The choice of sierpinski pretty much demonstrates that the "field of
research" into this category pretty much withered away a dozen years
ago, or more.

Thanks for your comments Mr. McLaughlin,

In the following paper
http://www.antlab.ee.ucla.edu/~johng/fractals/puente.pdf you
see a sierpinski construction containing 1 triangle gasket with 4 additional
sierpinski subgaskets.
The perfromance is mildly impressive. For example, the 5 gaskets seem to act
as 5 tuned
"bowtie antennas" with the resonance points divided by 2 (with the slight
exception of first
gasket to 1st subgasket), a distict advantage for hams.What this means of
course
is a multiband, multi-resonant antenna, with a possible infinite number of
subgaskets, although the
paper deals with only 5. No tuner should be required (except for 1st gasket
to 1st subgasket).
Or. for a dipole, none of those LC circuits need be added to the dipole
(ugh) to have
'resonance' at several bands. For each band, you just construct more
triangles.
The input return loss is rather good as well. I would really approeciate
your comments
if you could take a look at the paper I referenced above.

Richard:

1. A realtively compact multiband antenna.

2. Number of bands is defined by the user by simply adding as many
subgaskets as is needed.

3. Not difficult at all to construct a wire antenna this way. Stranded Cu wire, soldering iron, solder, wire cutters, nylon rope to suspend to inside of roof.

4. Resonant points of each gasket divided by 2. Thus no tuner.

When I get the time I hope to construct one. I need only to calculate the dimensions of the outer triangles operating as a dipole. Dimensions of the inner triangles (subgaskets) are based on the outer bowtie so no need for calculating (other than simple arithmetic).

Cecil,

I don't recall just how you became such an expert on optics, but your proposed use of constructive and destructive interference is not the way to calculate bright and dark rings. Great for handwaving explanations, or textbook explanations, but close to useless for detailed calculations.

In the real world most most problems of interest are not simple one dimensional set-ups with ideal lossless components. All of your nice power equations with cosine cross-terms get completely unwieldy in the real world.

Do you even wonder why you seem to be the pioneer in trying to apply constructive and destructive interference to HF problems? Do you suppose that no other smart folks ever thought along the same path? Do you suppose there is a reason why essentially all of the textbooks and scholarly writings on transmission lines virtually ignore constructive and destructive interference for detailed calculations?

You have recently demonstrated that you can get exactly the same answers as Keith, Roy, and others. However, beyond satisfying your own needs, you have demonstrated exactly nothing in addition to the results available from conventional analysis. That is dancing on the head of a pin.

There is really no particular need to discover "where the power goes". The equations for ordinary classical physics are self-consistent. If one gets the fields analyzed correctly, or equivalently the voltages and currents, then energy and power will take care of themselves. You simply will not find a case where all of the forces or fields are worked out correctly but the energy is not conserved.

You did say HF didn't you? If by that you mean 10M, yes, the
intricacies are within the scope of manageability. However, this then
dismisses the "multiband" nature, unless you are now talking VHF/UHF.

>4. Resonant points of each gasket divided by 2. Thus no tuner.

A Gamma match does much the same thing (no tuner). As for the
"resonant points" - again, easier to write than to demonstrate (let's
just simplifiy this and say impossible).

>When I get the time I hope to construct one. I need only to calculate the

Which returns me to the rhetorical question of what's your time worth?
Which fractal are you choosing? What application is it for? What
characteristic are you trying to optimize?

I ask this because:
1. It will take longer than with a conventional design;
2. It will not necessarily be the best fractal selected;
3. It may be inappropriate to the application;
4. You may stand to lose gain, BW, launch angle, or suffer match.

I was wondering if it's possible to shorten the radials from the standard 1/4 wavelength to another value, a smaller one. For example, in a 20 meters antenna, which is the best value of length for shortened radials or, in alternative, until which value is possible to go to without superlosses?
Thanks in advance

First of all, in googling these antennas I happened to come across your website and I found your discussions on fractals interesting. You do overal seem to have an intellectual bias of the designs as being mediocre, something that I don't necessarily disagree with for many applications but in my opinion your brush of mediocity is quite broad. For example, I don't think you have considered sierpinski carpets as a solution for a specific problem not shared by all hams, or possibly yourself, that is, the construction of a better than mediocre stealth (attic) antenna that is multiband by frquencies dividied by 2, balanced (resonant without ground) and easy to construct with wire. Repeating your premise above:

1. A Sierpinski carpet antenna can also be defined as a fractal antenna.

2. All fractal antennas have no more presumed benefit than a random wire pattern.

3. Therefore sierpinski patterns used as an antenna have no more promise than a random wire pattern.

I disagree with the above, or let me say, the logic is not convincing.

A random wire pattern would require a tuner. It would not have resonant points divisible by 2. It might not be compact. I must respectfully disagree with your premise. It is known that the bowtie construction works and has gain. Sierpinski acts similar to a repeating pattern of bowtie antennas of Fr/2, (we can do the same thing with dipoles but with less gain). That is why I say don't get hung up on the word "fractal". Doing so can paralyze the thought process with a mental roadblock. Because of negative or mediocre prior experience when analyzing antennas that are purposely constructed as 'fractal', it becomes impossible to consider this construction as a possiblly advantageous solution (for stealth situations in my case), just

because it also happens to be 'fractal'.

Thank you for your comments and thanks for the information on your site. I would caution however that there are many papers on the net that seem to give more possibility of success to sierpinski than you give to fractal designs in general.

Which means, that contrary to all the earlier assertions,
an energy+interference analysis works. The analysis that
Roy called "gobbledegook" caught an error in his own data
that he had overlooked for many years and about which he
had made some false technical assumptions which he promoted
on his web page.

If an energy analysis provided nothing more than uncovering
the errors in Roy's math and concepts, it was more than worth
the effort.

> There is really no particular need to discover "where the power goes".

Maxwell and Bruene have been arguing about such for 20
years now. The need to discover "where the power goes"
apparently exists for them and others.

If you, like Roy and Tom, don't care where the power
goes, that OK, but please don't try to present yourselves
as experts on a subject you don't care enough about
enough to have ever studied it in detail.

If radials are buried, their velocity factors may be
something in the ballpark of 0.5. That's certainly a
shortening effect.

With elevated radials, the radials can be shortened
and the vertical element lengthened to maintain
resonance. Radials can also be shortened by loading
each radial with a coil.

==========
It is my understanding that when radials are on the ground or buried
,their length can be any hence also shorter than 1/4 wavelength ,but
when very they are very short ,more of the same will give an improvement
especially when on dry ground.
When radials are above ground like when part of a vertical antenna
system fitted on a roof the quarter wave radial(s) ,at least 1 for each
band , are required ,since then they are 'the other half' of a dipole.

Yes, I need to spend more time calculating the lengths os the gaskets and I
haven't done that yet. However, it is an antenna construction so coil or
capacitive 'shorteners' may have to be tolerated, reducing the gain.

Hi Dan,

55 word sentences with 8 or 9 constraints follows from the topic of
fractal antennas. Antennas that perform better are often stated
simpler.

>Repeating your premise above:
>
>1. A Sierpinski carpet antenna can also be defined as a fractal antenna.

A fractal carpet can also be defined as a fractal? Was that one of my
premises?

>2. All fractal antennas have no more presumed benefit than a random wire
>pattern.

Presumption is in the mind of the presumer. If you find that as one
of my premises, it was attended by far more qualification. Fractal
antennas exhibit considerably different characteristics compared to
random wire antennas. Does this qualify as a benefit? It depends on
the application.

>3. Therefore sierpinski patterns used as an antenna have no more promise
>than a random wire pattern.

I don't think I made simultaneous premises/promises. However, this
argues what promise has been made; and it necessarily follows that
some application has been suggested. I know full well I've offered no
applications as a premise.

>I disagree with the above, or let me say, the logic is not convincing.

To say the least.

>A random wire pattern would require a tuner.

So do many fractals. Fractal does not mean resonant. Where it is
resonant, it does not mean it matches.

>It would not have resonant points divisible by 2.

What antenna does?

>It might not be compact.

Given the necessity of application, neither might a fractal.

>I must respectfully disagree with your premise.

I offered none to disagree with.

>It is known that the bowtie construction works and has gain.

All antennas have gain (directivity, properly) - even negative gain.
This a property of every antenna. That an antenna "works" necessarily
brings in the concept of application - there is sure to be one that
"works" better than the last.

>Sierpinski acts similar to a repeating pattern of bowtie antennas of
>Fr/2, (we can do the same thing with dipoles but with less gain).

"Similar" stretches to cover a lot of poor fits. A repeating pattern
is not a virtue as there are MANY inferior antennas that so qualify.

>That is why I say don't get hung up on the word "fractal". Doing so can paralyze the
>thought process with a mental roadblock. Because of negative or mediocre
>prior experience when analyzing antennas that are purposely constructed as
>'fractal', it becomes impossible to consider this construction as a
>possiblly advantageous solution (for stealth situations in my case), just
>because it also happens to be 'fractal'.

Well, in fact I can suggest many better antennas that are either
fractal or not - so there is nothing about the word fractal to bother
me.

>Thank you for your comments and thanks for the information on your site. I
>would caution however that there are many papers on the net that seem to
>give more possibility of success to sierpinski than you give to fractal
>designs in general.

I suppose I could give more possibility of success to one fractal than
I could give to fractals in general too and I have on probably several
hundreds of pages. The statement is not remarkable although the bulk
of data is.

Those papers you've come across came years after my work so I don't
know what they contribute as new insights; they've yet to break new
ground and they are novel only to the writers.

OK, I've returned to your original post to find you want:
1. A 40M antenna in an attic of unspecified dimension;
2. 10dB gain;
3. 25% bandwidths;
4. VSWRs at multiples of lambda at 2X.

By the numbers:

1. That can be done, yes, certainly, most assuredly, without equivocation - maybe if your attic is large enough.

2. This is not demonstrated in your reference paper (and I would suggest no where in the known world). However, for the benefit of the doubt, what do you mean by 10dB gain? With respect to what (dB can compare numbers, any numbers, but this is about antennas and there are simple conventions that resolve this nebulosity).

3. You want that to go with gain too? No.

4. Again, your reference paper nowhere exhibits this property, and again it would seem unlikely to find without hi-grading a lot of designs. It is not inherent in the class called fractals.

Your suite of "wants" contains conflicts in fractal design. To put it in a nutshell, you would have to read a considerable volume of work on the topic (much less antennas in general if the word fractal is too laden with issue) to allow any other conclusion to emerge from the general consensus. That outlier would be an exceedingly rare breed, and in all likelihood a fluke of misunderstanding; because, no, arriving with 1,2,3, and 4 intact is not achievable.

Still and all, I would applaud your attempt. Everyone needs to build at least one fractal in their life.

Hi Dan,

A fan dipole does not. It is not self similar at all scales, a
fractal is. The sierpinski easily qualifies on many levels.

>Yes, I need to spend more time calculating the lengths os the gaskets and I
>haven't done that yet. However, it is an antenna construction so coil or
>capacitive 'shorteners' may have to be tolerated, reducing the gain.

That would be unfortunate. The fractal can manage those issues for
itself. Calculation is plug-ordinary. You only need one successful
design and simply scale it to 40M.

>>>4. Resonant points of each gasket divided by 2. Thus no tuner.

Within the error of not being 2:1 (and notable not between the
fundamental and the first harmonic typical of most antennas);
trivialities aside, yes, it does support your statement.

So, it should seem that a 40M implementation is conveniently within
scaling from this paper.

However, as we close in on the 10th anniversary of publication, not
much about fractals has advanced beyond what was already known then.

Copy the CD to its own directory on the HD, then create an icon to the
pdf that is the index. You should be able to find the icon for the
book. Use that for the icon image.
As the book is a series of linked pdfs you only need the starting one
which IIRC is 000.pdf or some such name. From there on it's just like
using the installed version.

At this point you can install the other individual programs.

>
>just treat it like any other file, copy the cd image or the entire

>
>then try to get their viewer working it should install, since you

Just use the latest version of Adobe's free reader.
Which BTW some of the older books would install their own "older"
version of Adobe reader over top of a newer resident version, which
was a very good reason for the copy instead of install.

2552. LPY antenna designs?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-24 06:40:43 UTC
From: K7ITM <k7itm@msn.com>
Message-ID: <49115b34-632e-4cc8-bac6-1e820995e6d3@u10g2000prn.googlegroups.com>
Source record: 27774

Anyone have any practical LPY (log-periodic Yagi) antenna designs they care to share? Something with about 4% or 5% bandwidth in the VHF/low UHF range should do well--the element diameters should be appropriate for scaling the design to my frequencies of interest. 10dBi or so gain is probably fine.

Cheers,
Tom

Any log periodic would probably fool most folks. You might even get
away with putting up a 80m-10m LP, and just say it's for big screen tvs

define "log period yagi"??? ramsey has a line of products that they call
'log periodic and yagi' pcb antennas that has apparently been smushed into
"LPY" as the prefix to their part numbers... but 'Yagi' antennas are one
thing, and 'Log Periodic Dipole Array' antennas are something else. The
only place they cross practically that i have seen is the use of a log
periodic section feed section in between yagi style tuned parasitic elements
to give a wider bandwidth feed point... in this case it is usually just 2 or
3 elements worth of lpda feeding the yagi which i have always considered
just a way to add buzzwords to your antenna design description.

longer fatter rods, more of them, add horizontal buried radials, the same thing you would do in any other poor grounding situation... except in sand its much easier to bury radials and drive more rods than if you are sitting on rock, so do more of it.

Roy, here's a quote from your web page:
"I personally don't have a compulsion to understand
where this power 'goes'."

How can you care where the power goes when you don't care
to understand where the power goes?

You also scream out:
"THE REVERSE POWER IS NOT DISSIPATED IN OR ABSORBED BY THE
SOURCE RESISTANCE."

I just presented a special case example where all of the
reverse energy is dissipated (converted to heat) in the
source resistance. All it takes is one example to prove
your above statement to be false.

Your web page even contains one of those special case
examples. When your load is 0 +/- j50 at the end of
a 1/2WL piece of 50 ohm line, the forward wave and
reflected wave are 90 degrees out of phase at the
50 ohm source resistor. Under that special condition,
all of the reflected energy is dissipated in the
source resistor. Your own example proves your statement
to be false.

Hello Francesco,

It depends heavily on the antenna. When your antenna is an
electrically half wave radiator, the input impedance is in the kOhm
range and "ground" becomes less important. Many CB 27 MHz antennas are
half wave antennas (without any radials). For other lengths, "ground"
is important.

The smaller your antenna the lower the radiation resistance (=higher
feed current), and the more important the "ground" system.

For fertile wet ground and buried radials, the 0.25lambda is no longer
a magic number as the attenuation is very high. For dry Rock/sand,
dielectric properties dictate and some standing waves appear in the
ground conductor. As long as the real part of the ground impedance
is less then the real part of the input impedance of the radiator, it
is OK.

If possible, I prefer elevated radials. In many cases, they can be
shorter than 0.25 lambda (add more of them). The disadvantage is that
your floating ground becomes capacitive and you get a common mode
voltage on the cable screen, so you should add a common mode choke.
When you make them very short, the electrical situation is upside
down: your radiator functions as ground and your floating radial
network is the antenna.

An advantage of floating radials and the high end of HF is that your
radiation center is higher and ground properties become less
important, so you can have less loss (also in nearby structures) and
less noise from electrical equipment.

To give a more precise answer, one need to know your local conditions,
structural limitations, frequency and antenna type to be used, etc.
For low frequency, "Ground systems as a factor in antenna

systems" (Brown, Lewis Epstein, 1937) maybe interesting for you in case of buried radials.

I know this doesn't answer your question, but I hope it will help you a bit.

Best regards,

Wim
PA3DJS

2563. Oddball Antenna Question?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-24 16:27:41 UTC
From: Jim-NN7K
Message-ID: <LWgwj.5835$Mw.1567@nlpi068.nbdc.sbc.com>
Source record: 27786

Don't know if can explain this the best way, but in the
late '50's, early 60's there was a 6 meter antenna,
that was a YAGI design, but with a TWIST (Literally).
The Reflector was Horizontal, the 1st Director was
VERTICAL, and the other elements were "Skewed" so as
to imitate a helix , over the length of the boom
(some 25-35 FEET).

A normal helix, if memory serves, is wound 1/4 wavelength
to obtain circular polarization-- and the same for
satellite antennas, cross polarized , and offset by 1/4
wave, (and fed either 90 , or 270 degrees out of phase
from each other . For Right hand, or Left hand circular.

My question is 2 fold: 1) Did the Long Design really
generate Circular polarization (-3dB down in ALL polarizations)
or was this tilting at windmills.
and 2), for Circular polarization, does the constraint of
1/4 wavelength need to be applied to a (given) antenna?

Reason for this is an antenna that will pretty much
avoid polarity shifts, during band openings, or am I
Halucinating again?? Your thoughts Please
Jim NN7K

Hi Francesco,

In the air:
You are going to need a tuner for a standard height antenna with shorter radials. Instead, you can try adding loading coils to each radial (about midpoint). This will take experimentation to achieve resonance. So plan on putting it up and taking it down many times. You will also need a good choke at the feed point (aka 1:1 W2DU BalUn); and another one a quarter wave down the line. Some who report here say you will need more radials the lower the antenna is, and the closer to ground.

On the ground:
As many small radials as you can make, as long as the radiator. If that is too long (will not fit in garden), then simply fill the area you can. "Fill?" For argument's sake (a starting point) a dozen or more 0.1 wavelength radials. If this is too long, increase the count and make them the maximum length you can.

Read Wim's advice for halfwave radiators. They have the reputation of being ground free, but it will ease tuning if you build some radials - whatever length, whatever count (not critical). If you don't build these; then matching becomes a function of line placement. If the line changes, so does the match.

To bad you can't get at the ReBar in the concrete pad your new house may
be built on. That grid, if tied together properly, would make a JimDandy
Low Impedance RF Ground.

Locate a piece of rebar in the concrete and carefully chip the concrete
away until you reach the metal. Then attach a heavy gage wire to the
rebar and close the hole with concrete patch. You will now have access
to the grounding grid.

As Richard noted, MOST Loran C Antenna Systems, are comprised of a
108" CB Whip and an Active Antenna Preamp specifically designed
for the 100 Khz Frequency and 100 Hz Bandwidth of Loran C Signals.
Usually it doesn't take much except a good narrow Bandpass filter
in front of a couple of Cascode JFets, to get a reasonable signal
level for the Units receiver, and normally, Notch Filtering, is
done at the Main Receiver and Controlled by the microcontroller
that runs the receiver, for interfering Pulse Signals.

Thanks, Dave. That is probably what I may do, I don't want to be putting in overkill for my situation (that would be rods every 8 feet all around the house and connected by #0 copper!). I'm more interested in grounding for electrical safety than lightning protection. I'll probably just put in two or three standard 8' rods and connect them with large copper cable. My question was aimed more at wondering how effective for this purpose a ground rod or three would be in sand......

And thanks to those who mentioned the rebar grid... but this house is on pillars, with rebar only in the perimeter foundation.... and well embedded in the center of the concrete, at that, so as to preclude any access.

For an electrical safety ground, you should follow the requirements of
the National Electrical Code (NEC).

I believe other folks have mentioned that when the radials are buried, no specific length is required for the antenna to be resonant. The more radials you use and the longer they are, the lower the loss. There's a point of diminishing returns for both length and number, and it turns out that if you have only a few radials, making them very long doesn't help much.

Elevated radials normally have to be close to a quarter wavelength long for resonance unless they're very close to the ground in which case they need to be somewhat shorter. You can use the same techniques to shorten elevated radials, though, as you do a vertical radiating element. You can add a loading inductance at the feedpoint or farther along each radial, you can use a capacitive "hat" at the end, or some combination of the two. And just as happens with loaded verticals, the result will be narrower bandwidth, lower feedpoint resistance at resonance, and potentially higher loss.

If you do a bit of analysis with a modeling program, I think you'll find that if you generate a circularly polarized signal, it'll become nearly linearly polarized once it reflects from the ground. And it's nearly impossible, and often undesirable, to prevent ground reflection at HF. There might be a way to generate a signal that's circularly polarized after reflection, but I don't know how to do it.

That was my thinking for electrical safety and not for RF. Local conditions vary and change over the years.

Ask the building inspector what is required for your area. In my area it is two 8 foot ground rods spaced so far apart. I don't deal with the codes so can not tell the distance, but it is probably around 6 feet apart and connected by a continious conductor back to the breaker box. I think it is atleast # 6 copper wire for the ground.

Whatever you do , connect all the grounds around the house together, including the antenna and cable/phone lines if you have them.

One should never have any rebar exposed to the air. It will rust and expand
breaking the concrete. If put in correctly, it will be about 3 inches
inside the concrete.

True, but rather impractical for most hams, I suspect. I would
have to run a #6 or larger cable over 100' to bond the ground rod just
outside my ham shack to the building power entry ground.

So.... would I be better off just relying on the wall outlet ground
to my equipment? I'm just looking for electrical power safety, plus a
little help in possible static dissipation.

Francesco L. wrote:
"I was wondering if it`s possible to shorten the radials from the standard 1/4 wavelength to another value, a smaller one."

Elevated radials are resonant, but the 20th edition of the ARRL Antenna Book has Fig 47 on page 6-26 showing radials shortened by capacitive or inductive loading.

Buried radials have their resonance swamped by earth conductance. Such radials are surely effective when the greatest current drops nearly to zero at the ends, farthest from the vertical radiator, No interconnections far from the origins of the radials are desirable as they only encourage circulating current which only adds to loss.

E.A. Laport has Figs. 217 and 218 on page 119 of "Radio Antenna Engineering" taken from Brown, Lewis, and Epstein which show field strength variies versus 2, 15, 30, 60, or 113 ground radials of 0.412 or 0.137 lambda, at antenna heights up to 100 degrees, so that you can see what the shorter radials cost you.

Best regards, Richard Harrison, KB5WZI

That kinda the same conclusion I came to, Roy.
Asked on the VHF reflector, too-- the antenna was
apparently made by Telerex, and called the "Spiralray".
But tho it was touted as one that would work with
BOTH polarizations, I always wondered IF it worked-
and IF so, WHY no one ever duplicated it!
Like SOME old memories about radio, guess this one is
(Like TVI in the AM days, on Ch#2) best FORGOTTEN!!

No Free Lunch--(sigh)!

I will take your word for it and presume that it also conforms to
code.

> So.... would I be better off just relying on the wall outlet ground
>to my equipment? I'm just looking for electrical power safety, plus a
>little help in possible static dissipation.

OK, let's say for the sake of argument that you did NOT do the 100'
tying together of grounds. Let's further consider why there are
ground rods driven and linked in the first place = all grounds are not
all at the same potential. Hint: ground is inhabited by both
resistances and currents. Those currents through those resistances
create a potential difference. I am not speaking of "static" but
honest to goodness 60Hz power.

I can full well anticipate that you are bridging this potential with a
coaxial cable out to a remote feed point - not uncommon at all.

Let's take that to be a fact and proceed to another common action that
is frequently taken. Let's say you are having problems with noise in
your rigs, or strange modulations riding on your signal, or tuning
issues. You might reach for the antenna connector behind your tuner.
The tuner is strapped to ground, and the cable's coaxial shield
supplies this ground to that remote drive point.

As you lean over the tuner, you hold it with one hand, you grab the
coax connector shell, unscrew it and as it separates from the jack
connection the ground currents seek the path formerly through the coax
shield and instead travel through you, hand to hand - across the
heart, and you are killed.

Where do we send the flowers?

p.s. By the way, all those problems I described that caused you to
remove that connector? They come from poor grounding exactly as

described.

no, but without the substrate the size will be larger and performance
different. the dielectric loading of the back halves of the conductors will
affect the overall impedance as well as the velocity factor. Oh, and don't
forget to copper plate your yard to scale up the sheet of copper they used
as a ground plane.

I used to work for Decca Navigator @ their US Mfg plant here in MD back in
the 70's, (we were working on a Loran-D rcvr) and I think that I might still
have some of the 100kc xtals used in the Loran-C receivers in the junk box.
If I can still find them - any interest?

Hi Dan,

As I pointed out earlier, if you find a working model, you need only scale. What I left unsaid (and I presumed was the natural understanding) is that it will exhibit the same characteristics.

Take away the substrate, and you take away (alter) some of those characteristics. Which one(s)? Good question. Examine the original model in the absence of the substrate and you will find your answer. However, this is cold comfort as no one has access to work that is 10 years old (and was probably never performed).

Well, in fact I doubt it will have much disturbance with the fundamental properties, but the details will certainly drift. That is, the fractal nature of the design still remains. It will not resonate at the same frequency, but its comb of harmonic action will probably match the published work (maybe, there are others here better versed in patch designs than myself). Certainly it won't perturb the far field action to any great degree. Most of the radiation lobes will probably look the same.

I do agree that the antenna is too big for my purposes so I am shelving the
Sierpinski idea. Thanks all, for your inputs.

Hi Dave,

I didn't read the paper close enough for the details, but from the description of the radiator it would appear that the copper IS the radiator, and it was etched from the sheet.

In other words building it on a substrate was more a mechanical consideration (and a way to ease the implementation of geometry) than it was an electrical (RF) consideration.

The whole purpose of wall outlet grounds is electrical safety. You should hope your wall outlet ground is connected to a ground system which conforms to the NEC. If not, you might be facing some hazards when using electrical appliances, and might have trouble collecting insurance money if an electrical fire ever happens. I don't see much purpose in making another ground system if your home electrical system is properly grounded according to code. If it isn't, you'd better spend your effort in bringing it up to code, then using it for electrical safety.

Something like this hapened at a repeater. The power company had lost its neutral comming into the repeater building. The antenna was going to be changed out and when the man on the tower unhooked the coax from the antenna (up around 100 feet on the tower) he got a bad shock. Good thing he had on a good full body safety harnnes.

The only ground was the tower ground as the ground wire from the meter or fuse box had been taken off. All the power had been comming through the coax from the repeater cabinet to ground.

Yes, that's the design. I have data on a couple that suggest a pretty
"flat" gain across a modest range of frequencies, with a relatively
abrupt drop in gain outside that range. Googling got me to the
printed circuit antennas (I guess for wireless networks and the like),
but they aren't suitable to scale for what I want to do--too many
things different about them (flat elements on a dielectric substrate,
versus round elements in air).

Cheers,
Tom

OK. I may now consider that my electrical outlet will provide the
necessariy equipment ground.

Just to present the facts, this is a brand new home with brand new
electrical service in a nearly new neighborhood with new electrical
underground services.... so I must assume that everything was done
properly and to new to have deteriorated.

Secondly, in reference to my grounding my equipment, No, I would
not be relying on coax shields for grounding. My reference to my own
ground system outside the shack was for a DC ground for each and every
piece of my shack equipment which would be tied individually to a common
shack ground bonded by large cable to an outside ground system.

(Richard, you anticipated my ground intentions incorrectly as I
would never use a coax connection for grounding....) But I do
understand ground currents.... so perhaps I'd be better off just letting
the equipment ground itself through the Outlet's little bitty #12 wire
all the way back to the meter box ground.)

> battle through your pioneering analysis technique.

I didn't say it had been resolved. Those guys argue
about real-world class-C amplifiers. I didn't want
to discuss sources at all but Keith led me down the
primrose path. :-)

The small part of the argument that I can resolve is
the ideal class-A voltage and current sources. But
perhaps that resolution will spill over into the
more complicated configurations. I don't recall
anyone else considering what effect interference
has on energy redistribution inside an RF source.

But I indeed do have it figured out for ideal linear
voltage and current sources. Not only does it agree
with the results of other valid analysis methods,
but it answers the question: What happens to the
reflected energy when it is incident upon an ideal
linear source?

Hi Ed,

I may have incorrectly anticipated, but you haven't really described
any ground out at that remote point that was tied into the safety
ground at the service entrance - unless it is in this reference to
"little bitty #12 wire."

Do you have remote power through 100' of #12? It isn't clear. If you
don't and the far end is floating perhaps you are driving a dipole,
that too isn't clear - so then, no remote ground is called for.

However, as you are 100 feet up, looking over the dunes along the
coast (I imagine) out over the sea, this is a natural site for a
vertical for DX. Ground would be called for and we return to
potential differences.

So, to reduce any future "anticipation," is the remote site bonded to
the service ground of your home?

Let me rephrase my situation.

New house near completion. My shack will be at the far corner from the power service entrance.

I was thinking of just putting a couple ground rods (bonded together) just outside my ham shack and letting them be my equipment chassis ground, probably through a #6 wire from shack to ground rods. My intent was primarily for DC safety, plus a little 'static' dissipation.

As pointed out by one of you guys, I should meet NEC code, which would mandate my bonding this separate ground I would install with the house service entrance ground. My problem with that is that it would require a run of cable from the ground rods at least 100 feet to get down and around the house to the service entrance. This is not really practical nor desirable on my part.

While I understand the potential for ground loops, I deem it a rather small likelyhood in relation to the static dissipation benefit I'd get with the closer separate ground I could install. Others here seem to disagree with me, so I closed my previous post with the comment that perhaps I'd be better off forgetting my shack ground and just let the equipment be grounded through the individual power cords to the outlet ground.

Now that I may have cleared my situation up, what do you guys think?

Ed K7AAT

PS: Richard, just missing a view of the Pacific... about a half of a mile away ... and I may reconsider a vertical antenna instead of the dipole I was going to use.

My attic is large enough for a bent full size G5RV with no bends less than 90 degrees. It functions (i.e. it and the feedline radiates well, roughly as designed, and little RF feedback comes back to the radio). Of course, it is multiband and I do use a tuner but I can bypass it and still get out on 40/80/20m. Ten meters is not so good with or without a tuner; 15 and 17 seem to be OK. I was thinking that if I could bend a full size G5RV and fit it in my attic (2 X 54 foot lengths), I should be able to put up a fuill size Sierpinski for at least 40m with no additional bending (it is already bent into triangles). However, as dave and you have pointed out, when you actually try to scale the thing, it is very large and the bent G5RV is still a better choice for me. Thanks for the suggestions. This idea is hereby shelved from my list of projects under consideration (more of them get shelved than implemented ;-))

If you are calling 'low band' those frequencies below the AM broadcast band, any antenna you use will be of compromise size (less than 1/4 wave tall, less than 1/4 wave ground radials and less than 1/2 wave high.) A full length dipole is probably a challenge.

That being said, I operate mobile HF mostly. The car body is generally a poor, but raised ground plane. On 40 and up, communications are competitive enough to make contacts and communicate during normal open band hours (give or take SW Broadcast stations.) Because of power restrictions, 60 Meters works well mobile as competition is restricted to ERP 50 watts as radiated from a dipole antenna. 75/80 Meters is tough due to band conditions and antenna size in wavelengths and the number of high power stations on the air.

Your ground plane antenna whether on the ground or in the air will likely be very short. Even though its height and the length of the ground radials (raised or on the ground) will be longer, think of the effect of the mobile. Even though it has a shortened ground radial system, it does work. If you can match the antenna, you can probably work with it.

My experience is that the better the ground and the longer the vertical element (within limitations), the better the antenna works. I doubt there is much data reflecting various lengths of shortened ground radials as there could be too many variations. However, there is a manufacturer who has a vertical trap-multiband antenna that uses one tuned ground radial for each band made up of helical wire and/or a loading coil.

If you can't make a full 1/4 wave vertical, then do your best to make it as tall as possible, as many, and as long radials as you can, or

make the antenna as high as you can with four radials as long as you can, maybe loaded by helical or loading coil windings.

I hope this helps

I still recommend just using the outlet ground.

I don't think you'd accomplish anything by adding the ground rods you mention, and it might even cause a hazard as some others have said. It certainly won't be any better than your household wiring system ground for safety or static discharge. What I would do is make sure all your equipment is grounded through the household wiring safety (outlet) ground. Its purpose is electrical safety, and that's what it's designed,

installed, and inspected for. Ungrounded equipment can be connected to grounded equipment or to the mains safety ground -- if it has a power cord, replace the cord with a 3-wire cord and connect the safety ground to the chassis and cabinet.

Hi Dan,

Fractals come with many promises, but ALL of them cannot be met by one design. The literature would suggest they can, only because they speak of the conglomerate of benefits without meting them out to those designs individually.

For instance, resonance may be found in a small footprint, but not gain. Bandwidth can be found in a design, but not a small one. Also with gain, this takes space. The fields that result rarely show any symmetry, so often times the best launch angle is into outer space (nearly all my research was with vertical monopoles), and shifting up to the next resonance twirls that launch angle like spin-the-bottle.

To close the matter, fractals exhibit every natural tendency as any conventional design when it comes to match/gain/bandwidth. Something is nearly always sacrificed. There are rare exceptional fractals, but they have all the winning quality of a Pyrrhic victory.

I would suggest you invest your attention towards an Off Center Fed Dipole with a 4:1 BalUn and heavy choking of the driveline along frequent intervals. It will exhibit your sought after resonance harmonics of the fundamental where they most useful feed point is at 40% from the end (although there are others as well).

For what would be a standard 80M dipole fed 10% from the end are resonances at: 3.7 MHz, 7.6 MHz, 11.4 MHz, 15.3 MHz, 19.1 MHz, 23 MHz and 26.8 MHz. Some of them are blistering mismatches (80M is not really a resonance, but merely a dip) but it goes with the turf.

Here's some G5RV information:

http://www.cebik.com/wire/g5rv.html
http://www.vk1od.net/G5RV
http://www.w8ji.com/g5rv_facts.htm

The standard G5RV performs well on 80/40/20/12m.
Not very well on the other HF bands due to high
SWR on the coax.

Roy, won't a c-pol signal remain c-pol after a low-angle terrain reflection, except that its rotation sense is reversed? (The magnitudes of the v-pol and h-pol reflection components are nearly the same, but there is a 180-degree phase reversal in the v-pol reflection with respect to the h-pol reflection.)

This has been applied with good results in analog TV broadcasts using c-pol, because a c-pol receiving antenna rejects reflections of the transmitted signal -- which effectively reduces the multipath "ghosts" seen on a TV set when linearly polarized receive antennas are used.

> Rhetorical response: Enjoyment is suitable compensation when one is having
> fun.

Very true. Many things can be made to radiate, bedsprings, gutters, and
one fellow even had a tube full of salt water on his jeep as an antenna.
And all of 'em probably had fun designing and building them. I'm tempted
to try the water one myself.

I wonder if a tree, which can be turned into an antenna without a lot of
trouble, could be considered a fractal antenna?

My referral to "low band dxing" was just incidental. That was because
info about ground radials are scattered here and there. My target is
to realize a 2 element phased array (which I'm already assembling)
completely homemade and was wondering about the impact that a few or a
lot of radials can have on the system. Obviously I'm talking about a
fixed station, not mobile. Anyway thanks for the contribution, much
appreciated, of you all.

Correct, Ralph. Also, NEVER allow the possibility of a lightening
strike to enter rebar in concrete. You will explode the concrete
because of the tremendous localized heating. There goes your
foundation and/or pad your house is setting on. The building
inspectors in Central Oregon do check the footings and foundation
before concrete is poured and would quickly notice a connection from
the rebar to the outside world.

After you take your first couple of lightning strikes you will feel
that a 100' of #6 ground wire to the power ground for the antenna
system ground is a simple requirementl.

I will probably never build another house but if I do, the first
consideration will be proper grounding for both NEC and lightning
protection.

Experience has led me to believe that if you cannot tie a new ground
rod back to the panel ground you should not have the ground rod.

Yes, a ground-plane antenna needs resonant radials or at least with its vertical radiator it needs to make a resonant system.

According to J.D. Kraus, radial conductor ground-plane antennas were originated by G.H. Brown. Story is that Brown said only two radials were needed (for equilibrium?). RCA`s marketing department insisted on four and that`s how it`s been ever since.

Interesting. Here in Florida, the lightning capital of the continental US, the ordinary electrical service grounding mechanism is *only* via bonding to the metal in the foundation. New house construction will not pass inspection without such a connection unless other more complex arrangements are fashioned. There are typically no driven ground rods, and water pipes are usually non-conductive. (The NEC no longer allows water pipes to serve as the sole ground in any case.)

Must be a recent rules change Gene. I used to manufacture and sell an instrument to the power companies in FL, a meter that they would connect between one 120 Volt leg of the service drop and the residential ground rod, and drive the rod for a 25 Ohm ground. Typically, if they were installing pad mount transformers for underground service, they would install another ground rod there.

The Withlacoochee Co-Op, which serviced some of the highest sand dunes in FL, would often drive 60 feet of ground rod to reach the required conductance.

In Low band Dxing and also QST there was information on the number of radials verses their length. If I remember correctly the basic information was that distances between the far ends (end that is the farthest from the feed point) of the radial needed to be some set fraction of a wavelength at the highest frequency to maximize the performance of a vertical with radials of any length. So as the radials become shorter fewer of them are needed to meet this requirement. This not to say that few short radial works as well as longer radials but for any length of radials there is an optimal number required and putting down more gains very little. For wave radial this number is 120 but far fewer are needed for say 1/8 wave radials.
I don t remember the wave length that the article suggested so I will not make a wild guess.

for hf you want to look for 'owa', "optimized wideband array" antennas, and
also for yagi designs with dual driven elements like the m-squared 40m4lldd.
The advantages are a wider swr bandwidth and perhaps an improvement in the
gain or f/b bandwidth. you may also find some info searching for

'lpda-yagi' hybrids, though probably most of those are more for vhf/uhf.

That's a true story, also related in Brown's autobiography _And Part of Which I Was_. Two radials are necessary for near cancellation of their fields, to allow a circular pattern. The marketeers felt that it didn't look symmetrical enough to be marketed as an omnidirectional antenna so insisted on adding two more.

Two radials produce a very circular pattern in a directly horizontal direction. The pattern becomes non-circular above and below horizontal, but only very slightly for moderate angles above and below. I took advantage of knowing that story when I was asked not long ago to design an omnidirectional antenna to go in a small essentially flat volume. It ended up as a variation of a ground plane with two radials, implemented as flat traces on a PC board substrate. I built a prototype with copper tape and had it measured in an anechoic chamber at a test lab. It had the most circular pattern the lab technicians had ever seen, better than their very expensive reference antenna. The extreme quality of the circularity was actually a lucky coincidence because there are factors such as feedline coupling which cause some variation even in a lab environment. But it left no doubt that the pattern circularity was in fact very good in spite of the apparently asymmetrical construction. Brown was right.

George Brown, one of the pioneers of television, was also the inventor of the turnstile antenna, widely used for TV broadcasting. And he's the Brown of Brown, Lewis, and Epstein's seminal paper on radial ground systems. He also had a legendary sense of humor. One of his most famous stunts was substituting a blue-dyed banana for the yellow one in a bowl of fruit used to test the first color TV broadcast, causing a great deal of head-scratching among the engineers at the other end trying to figure out what was wrong with the color transmission. Walt Maxwell, W2DU, worked with Brown at RCA.

A head-on reflection to a flat surface results in the polarization sense reversal you mention. But reflection at a shallow angle doesn't. To see why, get the EZNEC demo program and run separate elevation plots of a dipole and a vertical, save the first plot, then superimpose it on the second. Begin with a perfect ground. You'll see that the field from the horizontal antenna is zero at zero elevation angle, while the field from the vertical is maximum. So if you reflect a circularly polarized signal from a perfect ground at a very low angle, you'll end up with a vertically (linearly) polarized field. The horizontal component disappears (that is, the field disappears each time it rotates to horizontal) because the reflection is equal in magnitude to and out of phase with the direct signal, so the two sum to zero at a distant point. If you look at a higher angle where the horizontal and vertical fields are equal, that's an angle at which you'd maintain circular polarization if those same two antennas were spaced and phased for circular polarization. At the elevation angle of the next null in the horizontal field, you'll again get a purely vertically polarized field. The conditions change when the ground has a finite conductivity, but you can use the same general process to understand what happens.

EZNEC+ or NEC-2 users can model particular antennas and directly see what happens to the polarization circularity. In EZNEC+, click on the Desc Options line, Plot and Fields tabs, and choose one of the circular polarization choices for Fields To Plot. Then run a calculation and look

at the plot. You get the polarization circularity by clicking the FF Tab button to show the pattern data in tabular form. The AxR column shows the axial ratio - the ratio of major to minor axis in dB. 0 dB represents perfect circularity, 99.99 dB means the field is completely linear, and in between represents various degrees of elliptical polarization. Begin with an antenna in free space and verify its polarization circularity in some direction. Then elevate the antenna, add a ground, and note the effect. A simple test antenna is a pair of crossed dipoles, very close but not touching, fed in quadrature, which will generate fairly good circular polarization broadside to the plane containing the antennas.

Hi Dave, and thanks for the reply. I'll try some searches on those keywords. Often, just finding the right keyword for a search is well over half the battle.

I perhaps didn't make it clear that I'm interested in optimizing the design for my particular application, which is up around 450MHz, so designs already at VHF/low-UHF are probably going to have reasonable element diameter-to-length ratios and may offer some ideas about good mechanical design. I'll happily spend some time with simulations to optimize the design for my application, but it helps a lot to start with a design that's close to what I want in the final implementation at least with respect to d/l ratios and percentage bandwidth.

Cheers,
Tom

Yes, that would agree with my experience. Also, I found it almost impossible
to tune into 17m. I was thinking about just connecting the ladder line
direct to the tuner and eliminating the small length of coax. That should
take care of the dissipation in the coax. That may not help with 17 meters
but it should minimize losses on the other bands.

Thanks for the reply. I was recalling the experimental results that RCA gathered in fixed and mobile tests in the Chicago loop when Ch 7 (ABC) installed an RCA c-pol transmit antenna on Sears Tower there in the 1970s. The ghost-reduction for same-sense c-pol tx and rx antennas was clearly evident, and quite remarkable.

The link below leads to a scan of several graphs showing why this was true for those near-in tests. RCA published a paper about it, which I will try to find and provide a link.

I don't know when the change was made. I discovered this rule when our house was being built in 2003. I noticed that there were no ground rods, and I started asking questions and looking into the code. Florida follows the NEC without exception. No modifications or local electrical codes are allowed. Of course the AHJ can override almost anything if he decides to.

As you know, the electrical utilities generally are not bound by the NEC or other codes. They follow their own rules. Also, there are a lot of preexisting cases where the foundation steel is not connected to the outside of the concrete. Ground rods must be used. In those cases your ground-checker instrument would still be useful.

Sorry, I can't get enough out of these graphs to come to any conclusions. But the equations for reflection coefficient as a function of polarization and ground conductivity and permittivity are well known (cf. Kraus, _Antennas_) and are used by NEC-2 and EZNEC. So conclusions based on reflection coefficients should be the same. Perhaps the multipath reflections involved in TV broadcasting are primarily from surfaces more or less normal to the radiated signal.

At my last QTH, I experimented with a variable length
matching section for a G5RV. Using the ladder-line-length
selector described on my notuner dipole web page, I found
the optimum matching section lengths for the G5RV on all
HF bands. It worked like a charm. Here are the optimum
matching section lengths that I measured.

Optimum length of G5RV matching section

75m 30.5 ft
40m 34.5 ft
30m 20.7 ft
20m 33.0 ft
17m 12.5 ft
15m 29.5 ft
12m 30.5 ft
10m 23.4 ft

I should have put a smiley face somewhere in the same zip code with the "recent" Gene. My experience ended in 1986 when I retired. Back then, (And for a good many years before) it was known as a "NEMA" Ground and 25 Ohms was the value.

I had a country home near Brooksville, FL, with some acreage and 5 towers (Tallest 160 feet) for a little contesting. Being there only on weekends, it WAS a fairly high maintenance property. Hardly a time when I went there that there was not evidence of some lightning damage, even with considerable effort to minimize it. Before cell phones, I was close to being the highest thing in the county.

> The dissipation in the source resistor is:
>
> P(Rs) = 50w + Pref
>
> How can anyone possibly argue that reflected power
> is *never* dissipated in the source resistor? :-)

It is time for a more complete analysis. For the sake of an
example let us set Rload to 150 ohms. That makes a nice
voltage RC at the load of 0.5.

Vs = 100 V rms

At the generator end
Vf.g = 50 V rms
Pf.g = 50 W avg

Vr.g = 25 V rms
Pr.g = 12.5 W avg

At the source resistor, before the reflection returns, the
dissipation in the source resistor is
Prs.br = 50 W avg
and after the reflection returns it is
Prs.ar = 62.5 W avg

Yup, it sure looks like that reflected wave is dissipated in the
source resistor since 62.5 = 50 + 12.5, does it not?

But let us examine in more detail...

Vs = 100 V rms
Vs(t) = 141 cos(wt)

Vf.g = 50 V rms
Vf.g(t) = 70.7 cos(wt)

Pf.g = 50 W avg
Pf.g(t) = 50 cos(2wt) + 50

Vr.g = 25 V rms
Vr.t(t) = 35.35 cos(wt-90degrees)

Pr.g = 12.5 W avg
Pr.g(t) = 12.5 cos(2wt) + 12.5

The power in the source resistor, before the reflection returns is
Prs.br = 50 W avg
Prs.br(t) = 50 cos(2wt) + 50

and after the reflection returns
Prs.ar = 62.5 W avg
Prs.ar(t) = 62.5 cos(2wt-53.13degrees) + 62.5

So, while the average powers seem to sum nicely to support the
claim, when the actual power as a function of time is examined
it can be seen that the power in the source resistor is NOT the
sum of its dissipation pre-reflection plus the power from the
reflection.

This solidly disproves the claim that the reflected power is
dissipated in the source resistor.

You may find the spreadsheet at
http://keith.dysart.googlepages.com/generator,line,load,reflection
useful in taking some of the tedium out of the calculations.
And yes, if your anti-virus tools do not like Excel macros, you may
have to invoke your authority over your tools. (They do know who is
boss, do they not?)

I will respond to your posted data after awhile. In the
meantime, let's correct the misconception contained in
your above statement.

No one is asserting that reflected power is *always*
dissipated in the source resistor so that discussion
is a dead horse. The assertion that I am making is:

Reflected RF energy is *sometimes* dissipated (converted
to heat) in the source resistor and sometimes it is not.
With an ideal voltage or current source, I can tell you
when it happens and when it doesn't happen along with
the quantitative values involved.

What is being questioned is Roy's assertion in his
"Food for Thought" paper. Quoting:

"THE REVERSE POWER IS NOT DISSIPATED IN OR ABSORBED BY
THE SOURCE RESISTANCE."

It seems clear that he is saying that reverse power is
never dissipated in the source resistance. That is
simply not true. Sometimes, there is nowhere else for
the reflected energy to go.

> And yes, if your anti-virus tools do not like Excel macros, you may
> have to invoke your authority over your tools. (They do know who is

I am reluctant to turn off my firewall and virus protection
while I download the EXCEL file. I once had a virus/worm
that even survived a reformatting of my hard drive. Apparently,
it was stored somewhere besides the hard drive.

Whoa Keith, Dr. Best's power equation that is being used
does not work for instantaneous powers. It is adapted from
the irradiance equation from optical physics which is a
time averaged power density. The irradiance equation
does NOT work for instantaneous powers even in the
field of optical physics and it is not supposed to.

Trying to use Dr. Best's power equation on instantaneous
powers is akin to trying to measure the feedpoint impedance
of an antenna with a DC ohm-meter. It is the misuse of a
tool. All powers or power densities appearing in the
power equation *must* be integrated over at least one
complete cycle. Instantaneous powers are simply excluded
from this energy model that we have been discussing.

Note that every voltage, current, and power in Dr. Best's
QEX article is an average value.

I have made absolutely no assertions about instantaneous
powers so your instantaneous power data is irrelevant to
my assertions. When I say "power", I am always talking about
time averaged power - never about instantaneous power.

You are free to make assertions about instantaneous power
but those assertions do not apply to my statements
about average power. They may be interesting to you but
have nothing to do with anything that I have been saying.

I'm in the process of building a homebrew Cobwebb Ariel.

I have found two different sizes for the twin cable elements, figure 8 42 strand 0.2mm, but on the Cobwebb web site it says figure 8 84 strand.

Also in the Cobwebb revealed PDF doc that I downloaded on page 5 it says each core is 42 strands of 0.2mm diameter and on page 7 of the same doc it says figure 8 84 strand. So I'm a little confused.

Does anyone know what is the correct cable to use, 42 strand 0.2mm or 84 strand 0.2mm?

Many thanks

As I read it, this is two-conductor "zipcord" cable, with 42 strands
in each of two separate conductors, for a total of 84 strands.

I doubt that the wire gauge or strand count is very significant, let
alone critical. You could probably build this from whatever sort of
stranded zipcord-type loudspeaker or appliance-wire cable you have
locally available (as long as it's not too thin-gauge) without
noticing a significant electrical difference.

2641. noise canceling Elevator /HF?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-27 02:38:44 UTC
From: ml <m@di.net>
Message-ID: <m-587AFE.21383526022008@news.verizon.net>
Source record: 27613

hi

I've had some interference from 1 to 30 caused by new elevator
equipment.

my building lookes like a long but narrow rectangle

it's about (rounding off) 100ft long maybe 50ft wide i'd guess

on each far end of the rectangle is an elevator room

both throw out same type noise

my antenna a horiz dipole center tuned (SGC) is ontop of the Eastern
one

some have recomended to help cancel the noise i try a noise
canceling device like a timewave anc4(others are simular so i'll use
anc4 as example)

i happened to have one hooked up anyway and already had a small
antenna extra up there i taped to the side of the elevator room it
picks up noise fantastic

the anc never really seemed to fix the noise i am really trying to
kill thou i will say over all in general every now and then some
noise (not by my building) can really be cancled by it when it
works it's great but it works so poorly for my situation*(not the
above elevator noise) but the other far an few randum noise i wouldnt
recomend one unless you specifically know it can help your specific
instance

sorry to a side track but it leads me to so why didn't this kill my
noise

(lets forget about that 2nd elevator for a second)

so turns out these things are designed to 'null' noise a)further away
than both your main antenna and noise antenna and b) presumes you can
sepereate the noise antenna from main ant.

i sorta understood 'b' didn't know about a

further the 2nd elevator is about 80 feet i can't tell if the
noise from it is getting over to the other side/elevator where my
antenna is aka east side if it is i realize my question below
becomes very complex

so question

how does one design a device ie what kind and whom can design essentially a anc4 like device that can create a null in the situation i have lets assume the 2nd elevator is not causing me issues

not even sure the theory behind it, i sorta understand how the anc 4 works thou

anyone have any ideas? any partial or total null could really help me out if it's poss to create one w/o sacrficing my rx sensitivity overall too much

Hi Myles,

There's the old saying that "if a little works, a lot works better."

But possibly not in this case.

If you have your sense antenna right up against the noise source, you are certainly inducing huge noise fields into that sense antenna's line. Much too much. Pull that sense antenna away 40 feet (put it between the two elevator sheds). 40 feet will still be plenty close.

Also make sure you have all lines going topside CHOKED! And in several places along the way.

Let's see...500MHz to 1.05*500MHz = 525MHz; boom long enough to get me
about 10dBi over that range. I'll scale it to my particular
frequencies of interest, so any other ~5% bandwidth in that general
vicinity of frequencies would be fine too.

Ok Dave, I will see what I have in the shed.
Trouble I have is that I only have a SWR meter to do the tuning and I have heard the thickness of the wire can change the length of wire used by quit a lot. So I really needed to get it very close for the tuning as I don't have an analyzer to use.

Thanks

hi Rich

thanks for the reply

i have a balun on both ends never thought of chokes hmmm maybe i
can rummage up some snap on of a partucular size/material think
dxengineering has nice chokes

the companies that make these noice devices say the above you
proposed won't work at all, however your idea is ceartainly worth
trying and a fun experiment only way i'll learn and know fer sure

and the chokes are easy to do can't hurt

as an aside:

i dunno why i was thinking the closer the sense at is the better but
not the case

> can someone explain how to connect 2 voltage 4:1 baluns in series to
> achieve 16:1
==========

With say one 4:1 balun having 2 windings Aa and Bb and the second 4:1
balun having 2 windings Cc and Dd with A & a etc the ends of a
particular winding , connect the windings as follows :

a to B , b to C , c to D

Connect grounded unbalanced side to bC connection

Connect the hot unbalanced side either to aB or cD connection

Connect balanced line between A and d

The above applies when the 2 existing baluns being wound with 2 windings
each with the 2 corresponding ends being A and B , a and b for one
balun and C and D , c and d for the other balun.

I should have made an ASCII drawing of the 4 windings in series ,but I
didn't expect it to be transmitted correctly ,so I hope the above
description makes sense .

Assuming you are trying to match 50 ohms to 800
ohms, the first one would need to be a 50:200 unun
and the second one would need to be a 200:800 balun.

Where does the 800+j0 ohm impedance that you
are trying to match come from?

Hi Myles,

What they may be talking about is noise that arrives over the air (radiation) won't be materially affected by chokes - or at least not enough. However, where chokes do work best is with noise over the wire (conduction) and your sense antenna sitting right on top of the elevator shack is tightly coupled (and why I suggested putting it further away).

>and the chokes are easy to do can't hurt

However, knowing their impedance characteristic is important because you may end up thinking they weren't useful for the wrong reason (they didn't present enough impedance).

A ferrite choke at the feed point consisting of 50 mixed beads of Amidon types #75 and #73 (or #77) over RG58 will be about a foot long. A couple more of these along the line (one a quarter wave away from the feed point for a low band, and another a quarter wave away at the high band) will help decouple it further. At a minimum, over the HF band it will present something on the order of 1000 Ohms to those noise currents traveling on the braid outer surface. The attenuation ratio of this Z to your front end Z is not very considerable (low teens of dB) but still useful. At the proximity you are with sitting on top of the elevator shack, distance with the square law will help far more - you only want to sense the noise, not pull it into your ham shack.

You will need to choke ALL lines going topside in this manner (your principle antenna, your sense antenna, your control leads to your SGC) such that this sounds like an investment of roughly 150-450 beads.

I would move the sense antenna first as that is the cheapest test for noise reduction that could bring the greatest return - pick the low hanging fruit first.

For wire running in a zip cord, point-to-point, you will use more wire
by twisting than running straight. This will affect the tune if, as
you say, length is critical.

As for being critical; there are many variables that contribute to the
state of tune, wire length being one of them, but not the sole
variable. The presence or absence of insulation, and how thick it is
will be another variable. Proximity to other materials in the
construction will be yet another variable. Proximity to other
environmental disturbances will contribute more variables. You are
almost guaranteed to not be resonant the first time.

Your SWR meter is sufficient for the purposes of tuning your antenna.
Simply take readings at close frequency intervals to chart a curve of
match (or mismatch as the case may be). Do this with the antenna IN
PLACE. Note from this curve how much you are off your desired
frequency. Make a slight (emphasis on slight) adjustment and repeat
the curve building exercise with the antenna IN PLACE. You will now
have a reference (the first curve) and a delta (the difference between
the reference and your second curve). This should tell you how much
you need to adjust to achieve match.

At these frequencies, the diameter of the wire is such a small
fraction of the antenna's length that small changes in the diameter
aren't going to matter very much.

As far as tuning and reproducibility goes, there's going to be a
bigger issue with this sort of antenna design (or any made from this
type of wire) - stretching of the wire under tension. This sort of
stranded, soft-drawn copper wire is prone to stretch quite a bit under
tension, both immediately and over time. You're likely to find the
antenna's tuning changing a bit, at least, over the course of its
lifetime, as the wires sag and stretch under their own weight.

Wire antennas are often made of "hard-drawn" copper wire, or of
soft-drawn wire which is pre-stretched to avoid such sagging and
de-tuning. I'm not sure whether zipcord-type appliance or speaker
wire could/should be pre-stretched in this way - I suspect that the
PVC insulation might be weakened by doing so and that the wire might
snap.

>Question about the elements.
>
>Does the speaker wire need to be kept very straight (no twisting) or doesn't
>it matter if there twisted?

I wouldn't twist it tightly - this _might_ add enough inductance to
alter the tuning by a detectable amount. A bit of loose twisting
ought not to matter. I don't think you have to be pedantic about
keeping it absolutely un-twisted.

As to tuning and SWR - as long as your rig has some sort of basic
autotuner that can handle a moderate SWR (say, 3:1 or better), and as
long as you get the antenna's tuning reasonably close (SWR minimum
somewhere inside each band you're going to be using), and as long as
you use a not-too-terribly-long run of good coax (RG-8 thickness
preferred), I really don't think you have to worry about trying to get
the lowest-possible SWR for the antenna itself. At HF, the amount of
"excess loss" in the cable, and in the ATU due to a moderate SWR is

not large, and probably will not make an appreciable difference in
your ability to either hear or be heard.

You can model that antenna with the free demo version
of EZNEC available from www.eznec.com.

Your configuration is unclear. How far above ground
are the ends of the inverted V?

how much power?

I used to have a dipole outside my apartment and the wires would touch some of the leaves/branches. I used a tuner at the feedpoint. On 40m (only), running 100W, it would arc to the tree on damp nights.

So, the real answer is, it depends. 100W dissipated in one spot could probably start a fire. a few watts lost in miscellaneous crackling and sparks, probably not.

If your wire antenna goes to an insulator, then to a rope/cable that goes to the tree, then you're probably much better off than just flinging the antenna wire through the branches. (the latter is popular with backpack portable...)

And, if you're that close to the tree, you're probably inducing some RF currents in the tree, so RF fields safety is an issue. Again, it depends. Power, operating mode, style of operation, whether there's any access controls to the area where the tree is, how high the antenna is, how big the tree is, etc.

What sort of accuracy are you looking for? At what frequency?
length of 116.63 ft implies you're working 75 or 80m? So the feedpoint
is 10m (1/8th wavelength) off the ground?

You'll have some directivity over an isotrope, but not as much as a
dipole. You'll almost certainly have some loss due to the ground.

27 degrees is the droop? Endpoints about 6 feet off the ground?

Assuming "average soil" and copper wire.

-2.5dBi straight up is the peak gain

At 15 degrees above the horizon, about -6dBi off the end, about -7.5dBi
broadside.

2659. Re: ? 75M Inverted Vee GAIN

Newsgroup: rec.radio.amateur.antenna

Source record: 27631

The gain and pattern will be very close to that of a dipole at a height of about 24 feet. Maximum field strength will be straight up, and quite dependent on the ground characteristics.

What's a point incident antenna?

Roy Lewallen, W7EL

ok thanks again rich, i shoulda been more specific the company made no comments about chokes only there noise cancling device those where my last comments about your comments which differed from their comments so despite all the commenting i will still try what you said cause it seems like it might work it seems logical

my coax for hf is LMR400 as far as chokes go i presume the types wouldn't change but i guess i'll need few more chokes on roof?

come to think of it i dn't have any chokes on my temp prob, sgc control etc i do on the shack end hmmm

i wonder if i cut power to the sgc and if i still get the noice it can't be a deffive sgc just to be scientific to rule it out

thanks rich for helping so much

I don't understand some of your terminology or precision.

However, as others have told you, a dipole close to ground has a major lobe that is upwards, and probably at the zenith.

The maximum gain depends on height and ground chacteristics. The article at http://www.vk1od.net/buddipole/index.htm shows the modelled pattern of a 40m inverted V and Buddipole and you will see from Fig 2 and Table 1 that the major lobe may be quite high (zenith), and the max gain may be quite high in the case of the inverted V (>6dBi). The Buddipole maximum gain is affected to some extent by the antenna's conductor losses, but greatly by the proximity to ground and losses in heating the soil.

Your antenna looks like it is intended for 80m (you leave us guessing), so it is at lower relative height than the inverted V in the article.

Owen

This is a Log Periodic design. Double booms, 1 inch square, spaced
1.4 inches c-c. Boom length ~55 inches.

Sweep for 500-525 MHz
Free Space Gain - 11.6 - 12.6 dBi
vswr <1.7:1.0

X is the position of the element along the boom.
Y is the length of each "half-element". With a double boom design,
one half of the dipole is mounted to one boom and the other half is
mounted to the other boom.

Coax attached to the front of the booms, shield to one, center to the
other. Do not run coax between the booms.

Booms can be electrically shorted to each other behind element # 1.

You don't have to be this accurate, my calculator defaults to 5
places. Simply convert lenghts to the nearest mm is the easiest.

x y
End 0
1 2, 5.78592,

Log-Yagi design. Four driven elements, reflector & director.
Probably about 8 dBi maybe.

Ele Length Position
R 1.019' 0
DR1 0.984' 0.168'
DR2 0.924' 0.266'
DR3 0.868' 0.359'
DR4 0.815' 0.446'
D 0.902' 0.742'

Split DR1-DR4 and transpose feed. Place hairpin at DR1 if needed
for matching.

You need to be aware that there's a good chance that this might not work, or at least not like you think it will.

An impedance transforming balun includes one or more windings connected across the two conductors. The impedance of the winding itself appears across the conductors as a shunt impedance. In order for the winding itself not to have an appreciable effect on the system, the winding impedance must be at least several times the impedance of the circuit to which it's connected. A rule of thumb is that it should be a minimum of 5 times the impedance of the circuit, with 10 times being better. That means that a 4:1 balun intended to transform 200 to 50 ohms would have a high-Z winding impedance of around 1000 - 2000 ohms. When a balun is designed for multiband use, the impedance is likely to be on the low side at the lower end of the frequency range, since this is where it's hardest to get high impedance. Also, if the impedance is too high at the low end, you can run into resonance or other problems at the high end.

The bottom line of all this is that you're likely to be putting a winding impedance of somewhere around 1000 - 2000 ohms in parallel with your 800 ohm antenna. If this impedance is pretty purely inductive, it will have a profound effect on the tuning of the antenna. If it's fairly resistive, it'll also dissipate a good fraction of the power you apply to it. So don't be too surprised if you see either or both these effects.

If you have an antenna analyzer you can terminate the high Z end with around 800 ohms of resistance and measure the input impedance. I'm sure you won't see anything that much resembles 50 + j0, at least not over much of a frequency range. If your antenna isn't resonant so it doesn't present close to 800 + j0 ohms to the balun, you'll likely see additional effects.

Thanks for both those designs. I'll have a look at them and see if I
can get reasonable modeling results, probably this weekend. I'd about
given up that anyone would have any designs to offer, and appreciate
that you put some effort into the replies.

Cheers,
Tom

The only thing left that I'm not sure about is the true length of the
element for 17m. I have read that the length on page 4 of Cobwebb revealed
for this band is wrong.

It says the Tapping point 2300 and the length 4400.

Is the Tapping point correct and the length wrong or are they both wrong?

What should they both be?

Many thanks

Here's a quote from "Optics", by Hecht, concerning power
density (irradiance). "Furthermore, since the power
arriving cannot be measured instantaneously, the detector
must integrate the energy flux over some finite time, 'T'.
If the quantity to be measured is the net energy per unit
area received, it depends on 'T' and is therefore of limited
utility. If however, the 'T' is now divided out, a highly
practical quantity results, one that corresponds to the
average energy per unit area per unit time, namely 'I'."
'I' is the irradiance (*AVERAGE* power density).

i.e. The irradiance/interference equation does not work
for instantaneous powers which are "of limited utility".

The cable used for the Cobwebb is:-

A very heavy duty twin cable with a 'figure 8' profile ideal for high
power speaker connection suitable for power amplifiers up to 500W
output.
42/0.15mm plain copper conductor
Rating 60V rms 6A
Overall size 5.7 x 2.9mm
Sheathed in white PVC with black polarity identification stripe

You can find it on the RAPID ELECTRONICS website at www.rapidonline.com
Part No. 01-0157.

Regards

Steve

It's called an isotropic antenna and that's where the
'i' in dBi comes from.

2674. Antenna suggestions for Vertex FTL-2011 mounted on Metal and fiberglass railroad equipment.

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-28 17:18:53 UTC
From: DVoeltz <dvoeltz@pie.midco.net>
Message-ID: <4c790678-bc7c-4ed4-a44c-05ed4635ae34@p43g2000hsc.googlegroups.com>
Source record: 27646

I'm new to this and need your help in selecting which antennas to use on my railroad motorcars.

The radio will be moved between two pieces of equipment. One cab has a flat metal roof and the other has a fiberglass cab. I would like an antenna that I can unscrew from the cab when traveling the equipment down the road on a trailer. The radio will be using the NARCOA licensed frequency of 151.625 MHz. I understand that this frequency is in what is known as the VHF-High Land Mobile Radio (LMR) Service band, and uses a modulation known as narrow band (5 kHz deviation) FM. I will be using a Vertex FLT 2011 40 Watt radio.

Based on the little I know about this, I understand a special antenna will be needed for the fiberglass cab since there is no ground plane. Both antenna will be mounted directly to the roof through a hole. The radio will be mount within 2 feet of where this hole will be drilled so I only need a short wire to connect from the antenna to the back of the radio.

If you can offer me suggestions as to which antennas to use, I would be most appreciative. Please excuse me if I misused some of the language of the hobby.

Thanks in advance.

Dave in Pierre, SD

>>
>> Marc
>> W5AMP

Marc - I have a thickly wooded side yard where I run 80 and 40 meter dipoles through and over a number of tree limbs. I don't believe that at HF frequencies (VHF & UHF is different) that the limbs and leaves make any significant difference - unless the RF power is actually shorting into the limbs and leaves. It will do this, if the wires are not insulated.

I run a KW (when needed) to dipoles that use #14 stranded house wire. The antenna wires are threaded through the limbs and leaves, resting on some of the branches. The dipoles work quite well. I do not see any fluxuation in the SWR when it rains or the wind is blowing, so I believe the nominal 600-volt wire insulation is sufficient to prevent shorting. (I try to keep the ends of the wires off the limbs.) The insulation on the wire will not hurt your radiated radio signal. Good luck. Andy K4YKZ (KN4YKZ in '58)

Oh, that would be an isotropic source. Gain relative to an isotropic source usually assumes that the source is in free space, so you get an automatic 3 dB of gain when you restrict your antenna to a hemisphere by adding a ground plane.

There's no single answer to your question, since the gain is strikingly different in each direction and at each elevation angle. The maximum gain occurs straight up, and you'd only be interested in that figure if you're doing NVIS work -- and it would vary quite markedly depending on ground conditions.

The simplest way to find the gain relative to isotropic (dBi) at any particular azimuth or elevation angle is by modeling. The free EZNEC demo program at http://eznec.com is adequate, and the Test Drive tutorial in the included manual takes you through the building of a similar antenna. You can easily modify the example to imitate your antenna.

Hi Steve
Do you have the correct measurement for the 17m element?

A lot of people say 4400 is incorrect as its too long.

Many thanks

Hi, Dave.
Sure looks like fun! Someone here in Redmond, Oregon has one of the
cars. Seen it parked on a truck and then on the ground in front of his
garage.

The antenna you want to use will in a large part depend on what
distance and over what terrain you need to communicate. If only a few
miles, then a simple ground plane antenna will work. The antenna will
add less than 18 inches to the height of the roof, so you may not need
to remove it for transport.

I am not familiar with the class of license you are operating under, so will not comment on antenna brands or installation. This seems to be a commercial type installation, rather than an amateur radio installation, so a licensed installer may be needed. If so, they will have the antenna information you need.

Best regards,
Paul, KD7HB

2679. SGC coupler to Dipole feedling question

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-29 00:51:16 UTC
From: Ed_G <Huckleberry_REMOVE_@bigvalley.net>
Message-ID: <Xns9A52AB752D939Huckleberrybigvalley@198.186.192.196>
Source record: 27651

Our ARES group plans on installing an Inverted V antenna on the second story flat roof edge of a local building. The antenna mast is 13 feet tall above the roof edge. The Inverted V will run parallel the edge of the roof and be approximately 35 - 40 feet per leg. Our primary operations will be 80/75/40M with a desired ability on 60M. The building custodian/owner will not tolerate open wire feedline with its associated standoffs due to aesthetic considerations, so we must feed this antenna with coax fastened to the mast. At the base of the mast, on the roof, we will be using an SGC-237 antenna coupler.

The above setup is a given, with no room for compromise.

My questions for this group are as follows:

Would we be better feeding the above antenna feedpoint with twin coax runs, using the center conductors as a 'balanced' feedline, or would we be better of using a single coax to the feedline? In either case, the coax runs will not exceed 20 feet and we must accept the losses in them. Email response from SGC seems to indicate we would be better off with a single feedline, but I am dubious about the SGC Tech Rep's response since he/she does not seem concerned about feedline radiation.

Also, what recomendations do you guys have for use of a balun? I believe, at the least, we would need a 1:1 balun at the Input of the SGC coupler so as to keep RF from getting back down the shield and into the building. SGC response seems to indiate they don't think a balun is necessary anywhere, which is another reason I am not thrilled with their response.

Comments?

I think you are going to have a difficult time operating on 80 meters if you
can not get around 120 feet of overall length. Then it may be difficult on
40 meters. If limiated to one single wire , coax fed, look at the off
center fed antenna.

Ideally there would be a ground plane for both, but it seems that most antenna mounts of the mag mount variety are getting their ground from the electrical system, then the body of the car. If the whole body is fiberglass, you could run some wires to use as ground plane under or on top of the roof. They won't be very long.

You might want to get an antenna that has a removeable mast so that you can just unscrew the antenna and leave the coax cable in place. If the whole thing has to go with the car, you'll probably want a clamp on.

re you averse to building your own antenna? a 1/4 wave ground plane would work very well, is easy to construct if you have some soldering skills, and is very inexpensive. Rough details are that it would take around 18.and a half inch wire for the vertical section, and 4 wires of that length for the radials.

If you are interested in that route, let me know and we can fill you in on the details.

If the SGC-237 coupler is on the roof and properly grounded, try it the way the SGC rep suggested. Any feedline radiation should occur from the antenna side of the coupler and might help with getting a bit more signal out. Go with the simplest solution first and run a single coax to the coupler from the transceiver. Maybe it will work just fine.

If there are problems with RF on the coax outer, add some ferrite beads over the coax to form an RF choke.

Look at more complex solutions when you have actually identified a problem rather than worrying in advance over something that probably won't happen.

Hi, I have put up a dipole and I admit it is not a very good one, about 20 feet up, approx 60 ft. It works great as a receiving antenna and I'm having fun listening, but so far no one can hear me. I have an Icom IC-735, and using SSB, the watt meter on the radio shows full power as I talk, but the watt meter on the tuner barely moves. In CW mode both meters go all the way. Is this a typical symptom of a poor quality antenna or does it indicate some other problem (besides my antenna making skills)?

Any advice is appreciated.

Thanks,

Jim

My SGC-237 is hard to mess up. Where ever you attach the wire to the
tuner is the beginning of the antenna. The coax attach will simply be
a matched line to the transceiver. I would be inclined to simply
attach the coax to the inverted V as you outlined and use it.

The antenna is in an environment that will not model well. The
radiation from the coax will have an effect on the aggregate
performance but nothing you can really measure.

Although I doubt anyone can explain just how it works, the SGC-237 and the wire you have described will work fine.

Modern antenna tuners perform a lot like Magic in my estimation.

My own feeble experiments have led me to believe that it is worthwhile to put an antenna analyzer on the configuration and make sure that the array is NOT resonant on any frequency of interest. The tuner seems to like that best.

Power supply: I have a very old telephone power supply tweaked down to 12 volts. I leave it on 24/7.

Thanks for the feedback, John. I imagine that we will end up doing
as you suggested. We WILL test the antenna on the ground with a
temporary mast to see if there are any issues, but we also realize that
things can, and probably will, change when it is permanently mounted on
the building. One of the reasons I am posing these questions here now
is that once the antenna is up, it will be difficult to get the
building personal (its a firehouse) to lower the mast for changes.
Its a rigid one piece aluminum mast that will be bolted at its base to
the building.

Hi Roy

to my understanding the load is purely resistive according to this
article http://www.cebik.com/wire/wbfd.html
anyway have a read and tell me what you think I am quiet interested in
others opinion on this one.
finding the right non inductive resistor has proven to be a challenge so
far.
no one told me home brewing antenna is a dark art :-)

Your antenna is already quite compromised with a
~490:1 SWR on 75m at the antenna feedpoint. The line
loss with RG-213 is about 4.5 dB and the tuner is
required to match 0.55-j48 ohms, another lossy
situation. Your antenna system efficiency may be ~10%.

How about turning your 13 foot pole into a radiator
and using the dipole wires for a top hat?

By the symptoms you describe, I'd say that the reason for the difference is simply that the meter on the tuner is much slower responding than the meter on the rig.

You may find it better to just wind your own transformer. 16:1 impedance ratio is 4:1 turns ratio. You can twist four wires together to make a quadrifilar cable that you use to put a few turns on a ferrite toroid. Then connect the windings all in series (say 1--2--3--4). The center tap, between 2 and 3, would connect to the coax feedline outer conductor, and the tap between 1 and 2 to the coax center. The outer leads--the start and stop of the whole thing--connect to the antenna. As for impedances of the windings and losses, this is one of those "your mileage may vary" things. I'd claim you don't need the impedance at the lowest frequency of interest to be too much higher than the 800 ohms resistive, since reactance is in quadrature to resistance and it's not the same as two resistances in parallel. For example, if you use a core that gives you, say, 0.3uH/turn, and you put 4 turns of the quadrifilar cable on it, the 16 turns when you put the four wires in series gives you about 256*0.3 or 75uH. At 3.5MHz (looks like the practical low end for that antenna), that's 1.65k ohms inductive, and that in parallel with 800 ohm resistive is about 650+j300 ohms. Through 16:1 (if the 16:1 is perfect, which of course it won't be, but should be decent), that's about 40+j20, which is about 1.6:1 SWR, which shouldn't upset the apple cart. Though coils wound on ferrites get resistive at higher frequencies, if you pick the right ferrite, by the time the balun's winding impedance is significantly resistive, it should also be quite high, so loss is not necessarily a big deal. Also, you can put about 2300pF in series between the balun and the feedline center conductor, and it will significantly correct the reactance at 3.5MHz -- and become progressively more like a short at higher frequencies, taking itself out of the picture. If the winding reactance behaves like a linear inductor versus frequency, the series capacitor will work very well. Assuming the idealized case--800 ohm resistive load, 4:1 turns ratio transformer that looks like a pure 75uH across the full winding--the worst SWR is 1.24 at 3.5MHz, 1.18 at 4.0MHz, and falls monotonically to practically 1:1 at 30MHz. (And I can get to even better match across the whole frequency range, even with only 50uH transformer inductance, by adding a cap in series between the transformer output and the antenna...) My advice: stay with a relatively low impedance, relatively few turns on the 4:1 turns-ratio transformer, and correct the low end with a bit of series capacitance. That will help you avoid problems with parasitic capacitances (etc) at high frequency. Use an appropriate core material that doesn't "die" and become resistive at 10MHz. Though my model is idealized, I expect you should be able to come acceptably close to it in practice.

Though my suggested design does not agree with Roy's suggested reactance 5 times the resistance it's across (my suggestion being only a couple times, or even less), I want to be clear that I'm in full agreement about the need to be careful about the _effects_ of low reactance at low frequencies, resonances and capacitive reactance parasitics at high frequencies, and dissipative ferrite at high frequencies. You're bound to learn a lot in the effort to get it working really right.

Cheers,
Tom

> and using the dipole wires for a top hat?

The aluminum 2" mast will be side mounted on the wood building... about 5 feet below the edge of the roof. The remaining 14 or so feet will be above the roof. With two 35 foot wires off the top, do you really think that would work to our needs better? There is one problem with this setup, though.... I do not think there is a suitable ground on the building roof. I suppose it is possible to run a simple wire straight down from the area near the bottom of the mast to the ground..... the SGC-237 would still have to sit on the roof and be connected to this now lowered feedpoint.....

I think it would be easier to extend the length of our inverted V legs. I had posted their length between 35 and 40 feet, but if we run out of building to extend the ends to, I suppose we could go on straight down from the end mounts, toward the ground a bit. Even an additional 10 feet could be had on each leg with the new ends being still 10 feet above the ground. It IS a wooden structure, for the most part.

Ed

John,

Any conductors or transmission lines carrying a net current (or common mode current) will contribute to radiation. If your meaning of "antenna" is something that contributes to radiation, then the feedline on both sides of the ATU might be part of the "antenna" no matter what you might declare.

If Ed connects parallel line from the centre of the dipole to the hot and common terminals of the ATU, there is likely to be common mode current on the parallel line adjacent to the ATU. If the only connection on the tx side of the ATU is the coax, then it will also have a common mode current adjacent to the ATU and near enough to equal to the common mode current on the other side of the ATU.

That is not to say it won't work. People regularly build antennas with radiating feedlines, some (mainly commercial interests) even call that out as a significant advantage.

Nevertheless, there are downsides and some measures to minimise the common mode current on the feedline may be warranted... or even necessitated down the track.

Ed has been deliberating over a solution to this problem for a long time. It has been discussed to some depth!

Owen

2693. RF Calculator Tool Online - Solve Antenna Equations and Electronic Circuit equations

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-29 07:14:58 UTC
From: EngineerEDGE <calculatoredge@gmail.com>

Hello Friends,

Check this website www.calculatoredge.com you will find several RF Calculator Tool, you donot need to learn the formula to solve the equations, if you have inputs then you can just enter into and get the equations solved.

You also get free magazine subscription on this website, I guess it is useful

Tom

2694. Re: Cobwebb antenna question?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-02-29 10:38:23 UTC

Message-ID: <ce6cfe15-f2cb-44fe-96c5-e55455486f22@d62g2000hsf.googlegroups.com>
Source record: 27666

The measurements in the booklet were taken from an actual cobwebb.

The lengths and tapping points for the Tee match, need to be adjusted
during the initial tests.

An Antenna Analyser is very helpful during set-up and you may have to
beg or borrow one for testing.

However, in tests, the following dimensions have been used
successfully:-

Band Element Length Shorting point
10M 2540 mm 1560 mm
12M 2930 mm 1790 mm
15M 3450 mm 2080 mm
17M 4060 mm 2220 mm
20M 5150 mm 2720 mm

Hope this helps

Steve.

that sounds like something is wrong. try a whistle, see if that gets the external meter to move properly. then try cw up in the ssb band and see that the swr isn't wildly different. make sure that the meter you are watching on the radio isn't the alc or swr or mic audio or compression instead of power output also, some radios use the meters for multiple things and it could change without you noticing from cw to ssb since cw doesn't have mic audio or compression levels.

I was thinking you could lay some radials on the roof
to obtain your ground plane. You could also insulate
the pole from the mounts using sections of PVC pipe.

> I think it would be easier to extend the length of our inverted V

I had assumed that your "no compromise" statement included
antenna length. A full-sized dipole would certainly solve
your 75m problem but then the full-wave dipole would be
mostly non-functional on 40m when fed with coax.

Here's another idea. *Change the pole support to fiberglass*,
use heavy duty 300 ohm balanced line, and run the 300 ohm
feedline inside the fiberglass pole to the dipole. You could
use the G5RV length of 51 feet per dipole element. With such
a configuration, the feedpoint impedance on 3.8 MHz would be
about 20-j130 ohms and on 7.2 MHz would be about 100-j450 ohms
which the SGC would have no trouble matching. This could
multiply your system efficiency by maybe 6-8.

Jim,
I'm wondering what frequency you are trying to use this antenna on?
If it's a frequency where the length of the antenna isn't even close
to the 'ideal' length, the readings would seem about right, sort of,
at least when comparing SSB and CW. What frequency(s)?
- 'Doc

(Receivers aren't near as 'picky' about somethings as transmitters
are. Dang near anything can be used to receive.)

Antenna tuners 'like' antennas that are 'too long' better than
antennas that are 'too short'. That doesn't say anything about how
well that 'too long'/'too short' antenna will perform, just that the
average tuner will find it easier to deal with one that's 'too long'.
(Easier to 'cram' more capacitance into a tuner than inductance.) If
this antenna is a doublet, 'balanced', why would you need a
'groundplane'? And while I'd guess that it'll never be 'ideal', the
building is acting as a 'groundplane' anyway, sort of.

I don't think you are missing anything; your comments sound reasonable to me. The building is the nearly new local firehouse HQ. The Chief and staff have outlined very strict parameters for our antenna location and setup. They fabricated the aluminum mast and will install it on the side of the building per their own design. Even at that, they gritted their teeth at the visual impact it has. No stand-off supported open ladder line for us! We must work with this and I don't see any feed alternative than coax. The only thing we 'may' have some flexibility with is the length of the antenna. (Sorry Cecil, I guess I should have mentioned that up front). We are limited to the length of the side of the building, which I estimated would give us up to 40 feet of element from the top of the mast. However, in hindsignt, I believe we could at that end point drop some additional length down off the end for a longer antenna.... would probably give us better operation on 75 & 80.

On SSB, no power output is produced until the carrier (which is later
suppressed) is modulated. Yeah, you could know this, but it is possible that
you do not. This is in case of the latter.

As the previous responder said (my memory is bad - sorry), if your meter is
slow, the modulated voice peaks may not show up on the meter.

Ok, first thing, NONE of the Lumped Constant Binary Switch Tuners like SGC's Knockoff of the SEA Design, will tune ANYWHERE within a few percent of the Natural Halfwave Point of the antenna. So you must design the Antenna, so as to move that Halfwave Point to a section of the HF Spectrum that you NEVER plan on using. Second thing, none of the SGC Employees around today, were around when this Tuner and it's Operating software was designed, and most don't have much experience with actual operational considerations.
Thirdly, After a lot of experimentation with the SEA1612b Series Tuners, from which the SGC's were plagiarized, when using them to drive a dipole, there are two schools of thought. One school says that you should add a 1:1 Balun on the output of the tuner between the RF Ground Stud, and RF Output Connection to make your Balanced Feed. Second school says to take the Feedline Coax, Dc Power Lines, and Tuning Feedback Wire, and wind them, in a Bifilar fashion on an appropriate Torriod to decouple the Tuner from Radio Feed and connect the dipole to the RF Ground Stud, and the RF Output Connection.
I have used both Systems on Maritime Mobile Limited Coast Stations, around Alaska, and find that they both work about Equally Poor. It should be noted here, however that Alaska is notorious for not having any kind of decent RF Grounding Soil, so usually this type of Antenna System works much better than an type of Longwire antenna that needs a good RF Ground, to work against. Where a GOOD RF Ground is available, (Salt Water) the Longwire Antenna outperforms the Tuner Driven Dipole, ever time, but without that GOOD RF Ground, the Tuner Driven Dipole works better than just about anything else, especially over a wide range of Frequency Bands available, in both the Maritime and Amateur Radio HF spectrums.

Get them to fabricate a piece of fiberglass tubing
and all your problems will disappear.

However there are umpteen circuits for a'peak-picker/holder' which with
a set suitable time constant will enable any meter to sense the peak
and hold it until the next peak. I don't mean just a simple capacitor

I fully agree, but we have absolutely no input in regards to the mast they have provided, and to attempt to persuade them otherwise would only jeopardize the situaion, so we must accept what they have provided and work with it.

There is someone, somewhere, who has the authority to
change the mast from aluminum to fiberglass for the
purpose of multiplying your radiation efficiency by
a factor of 7. I would seek that person out and bend
his/her ear.

Dunno. Seems a bit strange if no one can hear you.
It sounds like you are using an average reading meter,
vs a peak reading meter.
In the case of an average meter, on SSB voice peaks
you will usually see about 1/3 of your actual output.
IE: with a 100w radio, I'd expect peaks of appx 35w
on the meter. Barely moving seems to be a problem.
Being as the rig seems to be doing full power in CW
mode, I doubt the antenna is the problem. As long as
the SWR is under 2:1 you should be doing full output.
It can probably actually be a bit worse, and still do full
power in many cases.
So that makes me wonder if you might have a mic drive
problem, etc..
What mike are you using? Most older icoms require a
mic preamp. If not, you won't get full drive.
And I think the 735 is one that requires the mic preamp.
Even my 706 requires a preamp if I'm not using a stock
mic. If not, I won't get full drive.
Try the stock hand mike, if you are using something else,
and see what happens.
Average meters will usually read only about 1/3 of actual
output, but barely moving the meter is not right, if CW
if reading correctly. You should see peaks of 25-35
watts if it's working right. Near full power peaks if using
an actual peak reading meter. Most passive "capacitor"
meter hang circuits only read about 80% of full power.

Also, anybody can make a mistake. I'm sure you know this already but is it possible that your drive setting on the transceiver for MIC (for SSB) is too low but the drive setting for CW is good? (Not sure if you could get a good reading on your transceiver if this were the case). MK has a more likely scenario.

Let us know what happened if you figure it out.

Believe me, Cecil, that is not the case here. This is a very small community. The Fire Chief and his Deputy have ultimate authority over this building. Besides, to attempt to go over his head would merely jeopardize the good relations we already have which allowed us to get this far anyway. We'll leave well enough alone and work with what we have. If it weren't for the fact that we need operation on 3589 & 3980, ~7090 & 7248, and hopefully 60M, we'd probably have just gone with a trapped wire antenna off this mast instead of using the SGC-237 (which we already possess).

Thanks.

Ed

Bruce,

Thanks for the response to my query. I have a couple comments to
these. One, we already own a new SGC-237 coupler, so that is what we
will use. Two, thanks for the info on the SGC personnel.... that
might explain why some of their responses to my emails didn't seem to
make sense... especially their comments about NOT needing any balun.

Three, and more direct to my initial questions, it appears we will be using coax between the coupler output and the antenna feedpoint.... up to 20 feet of low loss... we'll just eat the loss. But more importantly, I had intended, and will proceed along the lines of your comments on baluns, by installing a 1:1 balun at the input to the tuner. This will, at least, keep the RF out of the building and our station location.

thanks.

Ed

2716. Coax Switching Boxes (receive only)

Hello,

I would like to purchase an "inexpensive" simple, coax antenna switch for occasionally switching two antennas into my scanner.

Freq. range up to about the scanners limit of 1.3 GHz

Receive only.

Looked at the Daiwa, and for the $ seems like the way to go, but I thought I'd ask first.
Any opinions on the Daiwa ?

Any others to consider also that aren't too expensive ?

Ace hardware has a coax switching box, I guess for TV's mainly, with pushbuttons.
Think this would do the job for my scanner stuff, or probably just junk ?
It's really cheap at about $8

Thanks,
Bob

A CATV A-B switch? It should only be a few dollars. Although the spec
may only be up to (say) 870Mhz, they are probably OK (for your purpose)
to 1.3GHz +.

Bob,
Receivers just aren't as 'picky' about switches as transmitters are,
so almost anything would probably work just fine. If you're into
making things instead of buying them, a look in the junk box would
probably be profitable. If not, then ... whatever grabs you.

The one parameter receivers are "picky" about is port-port isolation.
Switches made for HF switching will likely have very poor port-port
isolation at VHF and above. The result is the receiver hears the selected
antenna and some of the unselected antenna. This may or may not be a
problem.

A decent cable TV A-B switch should have an isolation of at least
something like 40dB at 870MHz. [I think I measured an old Jerrold switch
as being around 70dB.] While probably less at 1.3GHz, it's probably
still sufficient.

Suggest you fit a pulley at the top of the mast such you can lower and
subsequently change the antenna using a halyard.

Ed, you would be Much Better Off, if they would allow you to use (2)
runs of Coax, side by side up the mast, and connect only the Center
Conductor of each, to the tuner, with the shield left open on each end
and sealed against water intrusion. Even if taped to the aluminum mast.
This would provide a much better situation than a single coax feed.
Also if you are stuck with a single coax, then make SURE, that the
shield side of the coax is connected to the Ground Stud of the tuner.

Well! That was part of my original question in this thread! I had
intended to do just that, but some here seemed to steer me toward a
single coax, including SGC personnel. I do NOT think we have any
decent ground at all available anywhere near the roof location where
this antenna mast will be located, so I was unsure if the twin coax
feed would be OK without grounding the shields. Left floating, I
don't know what effect, if any, we will have for incidental radiation.
One thing for sure, it won't be any worse than using a single coax with
no balun at the feedpoint.

It the goal was to sabotage our communications, they would have denied permission to use their facilities totally, let alone, not have purchased and fabricated the nice aluminum mast which they did for us. Admittedly, they seem overly concerned with the visual impact of things, but beggars can't be choosers! Tnx.

My expertise is weak in this area, but just guessing.... using twin coax in the above configuration, if the shields were grounded, would allow the feedling between the antenna coupler and the feedpoint to be 'balanced' and yet the shields would not radiate as they would with a single coax run.

Perhaps others, here, will either expand on this, or correct my misconception.

But that is not what was said. I read it to say "with the shield left
open on each end".

> allow the feedling between the antenna coupler and the feedpoint to be
> 'balanced' and yet the shields would not radiate as they would with a
> single coax run.

Bunk. The only reason the shields would not radiate would be if they
carried equal but opposite currents. That is most unlikely in this case.

Let us just consider a simple example. Assumption is that skin effect on
the coax is fully effective, a reasonable assumption at HF.

Make a quarter wave vertical of a piece of RG213 supported on sky hooks.
Make no connection to the shield at either end, and connect the feed line
between a ground plane / counterpoise / whatever and the centre conductor
of the vertical piece of coax.

What current flows on the outside surface of the vertical coax?

The current on the outside surface of the vertical coax adjacent to the
bottom end of the isolated shield is the same as the current flowing on
the inner conductor adjacent to the same end of the shield.

Does the outer conductor 'shield' the vertical so that it will not
radiate?

No, the outside surface of the shield is the radiatior, it just has a
quarter wave o/c stub in series from the feedline to the radiating
element.

Side-by-side runs of RG-11 (Z0=150 ohms) would reduce
the SWR on the coax and change the impedance seen by
the tuner from 0.3-j69 ohms to 1.9-j154 ohms which is
quite an improvement. You can increase that feedpoint
impedance even more to 2.5-j170 ohms by using side-by-
side runs of RG-133 (Z0=190 ohms) if you can find it.

I forgot to say that these figures are from EZNEC which
assumes lossless feedlines. Real-world impedances would
be much higher due to coax losses.

If both shields, (ungrounded) are tied together, and the two
center conductors are acting as a 'balanced' feedline, how can current
flow on the outsides of the shields, if the interior currents of the two
center conductors are always 180 out of phase?

"Left Floating" so that there is less Capacitance to RF Ground, and more
distance between the vertical parallel Feedlines. It would even help
if you can use twin Coax Runs, to put them on opposite sides of the
Aluminum Mast, which would give you more separation with the same
Coupling Capacitance to the Mast. Capacitive coupling to RF Ground,
is the Killer here, and you MUST reduce that, as much as possible,
if your system is going to have any chance at reasonable operation.

2737. Matching Coax Impedance: To Receiver or To Antenna ?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-02 19:36:58 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <ysOdnUH_wMtKnFbanZ2dnUVZ_vCknZ2d@comcast.com>
Source record: 27559

Hello,

Have a Scantenna antenna (receive only) in attic.
It came with 75 ohm RG 6 coax, so presumably the output has a 75 ohm impedance.
How this varies with freq. I have no idea.

Have a new scanner that says to use 50 ohm coax.

From old posts, the consensus seems to be that it doesn't matter if you use 50 or 75 ohm coax for
a run that I have of about 50 feet.

Do you folks agree with this ?

From a somewhat more rigorous and theoretical view, should the coax, even it hardly matters, be matched to the antenna output impedance, or the input impedance of the scanner ? Why ? (again, receive only)

Any thoughts on this would be most appreciated.

Thanks,
Bob

At both ends?

This is the first mention of shields tied together, I certainly didn't read that into Bruce's "with the shield left open on each end ".

> center conductors are acting as a 'balanced' feedline, how can
> current flow on the outsides of the shields, if the interior currents
> of the two center conductors are always 180 out of phase?

The analysis in this case is different, but if I understand your scenario, the outer surface of the two coaxes which are tied together at both ends but connected to nothing else still carries the common mode current. that exists on the two open wire conductors just prior to entering the coax assembly. No, you cannot guarantee that those currents are equal and opposite, ie that there is no common mode current, and the common mode current will flow entirely on the outside surface of the outer conductors of the coax assembly when connected as you now propose.

Bruce hasn't explained what his configuration is supposed to do, so we are still guessing about that one.

There is no answer to this problem, because the problem is ill defined. You have just added a new element in tying the shields together. Other questions exist like what other connections exist between tx feed line, ATU, ant feed line, mast, roofing / rain gutters, any other conductors.

Somethimes knowing how to describe a problem is knowing the answer to the problem... or conversely, not knowning the answer is the result of not knowing how to describe the problem.

That's because I added that to the mix. Bruce's comment was a suggestion for me. I have not done this yet, but my original post under this thread was solliciting comments on using twin coax to feed a balanced antenna, or using a single coax feed under the specific set of circumstances I outlined.

About the common mode current.... please explain how this would be an issue with the outer shields of two coaxes, shields tied together but going nowhere (no ground), and the balanced antenna fed by the two center conductors. I do not see common mode current being a factor, but I'm willing to listen and learn.

Please read my response and question just posted to Owen. With both
shields tied together, but not grounded, nor connected to the antenna
either, I do not understand how common mode current is an issue on the
shields.

We could use the mast as a physical separation as you suggested, (
the mast is not grounded, either, but again, what is the point, if the
two coax shields were "as one" anyway?

Ed

Hello Bob,

For reception with a scanner, using 75 Ohm instead of 50 Ohm cable
will not make a big difference.

Your Scantenna will also not have a 50 Ohms output impedance all over
the band. It will be higher, lower and/or reactive, depending on the
frequency.

Your scanner will also not present 50 Ohms to the antenna all over the
tuning range. It is even unlikely that your scanner will have maximum
sensitivity when driven from 50 Ohms all over the tuning range. There
will be frequency ranges where maximum sensitivity (input power, not
voltage) will be reached with other then 50 Ohm output impedance of
the source.

When you should do rigorous measurements with your setup (that is with
RG6) with respect to a 50 Ohm setup, there will be frequency ranges
where your setup will give best sensitivity and where the 50 Ohms
setup will give best sensitivity.

So Bob, don't worry when using RG6 75 Ohms coaxial cable.

Best regards,

Wim
PA3DJS'
www.tetech.nl (Dutch).

> That's because I added that to the mix. Bruce's comment was a

Ok, well here is a model to shape your thinking and moving the goal posts.

At frequencies where skin effect is fully developed, and that is a reasonable assumption for most practical coaxial cables at HF, the current on the inside surfaace of the outer conductor is equal to but opposite in direction to the current on the outside surface of the inner conductor. This is TEM mode propagation.

At the end of the isolated outer conductor, this current must flow somewhere, and it flows around the end onto the outside surface of the outer conductor (effectively changing direction as it does so). So, at that point, the current flowing on the outside of the outer conductor is exactly equal to the current flowing on the outside of the inner conductor.

Leaving aside the effects of changing Zo by substitution of coax for plain conductors:

If you use two coax lines in parallel with the shields isolated, it makes very little difference, the current that would have flowed on the two plain conductors now flows on the outer of the coax lines. The common mode current is the sum of the currents in both coax shields, as it would be for plain conductors.

If you join the shields together at each end, the sheilds together now carry the common mode current. A different equivalent circuit, but almost the same outcome.

Most of these 'shielded solutions' arise from a lack of understanding of how the coaxial transmission line works in TEM mode.

For example, I saw an ham advise someone that station ground connections were subject to noise pickup and the best improvement he could make was to shield the ground lead. In his case, his shack was on the first floor of the building, and his 7m vertical ground lead to the earth stakes etc was a source of noise, so he used 7m of RG213 with the shield and inner bonded to the earth stake and the shield left isolated at the top end.

Firstly, this is not a 'shield' at radio frequencies, but what he did achieve was to insert a s/c stub in series with his station ground conductor. The impedance of that series stub at 7.1MHz is 3056.20-

j1509.30 ohms... not a good outcome.

It might have 'fixed' his RF feeback problem, but it didn't improve the station earth at all, it degraded it severely.

Owen

The last paragraph above is where I lose you..... when the shields
are joined together. Yes, I understand inside the shield RF
current flowing around the end and to the outer side.... HOWEVER, the
OTHER center conductor is inducing RF current flowing in the opposite
direction. Since both these inside currents are 'shorted' at the ends
of the two shields, I fail to see how you can have any current flowing
on the outer shield since the two opposite currents should cancel....
????

I already said that as I understand your variable configuration, it is most unlikely that there is zero common mode current, or close to it.
Irrespective of the magnitude of the common mode current, the mechanism is that the coax doesn't 'shield' it.

No, I wouldn't say "shield" would be a proper term, either. But I would suggest that a "cancellation" similar to radiation in a balanced feedline, would be pertinent.

Using the center conductors of two pieces of coax, with shields bonded together, does create a balanced transmission line. Its characteristic impedance is twice that of the coax itself. The higher impedance of this feedline will cause the voltages on the line to be higher than on a single coax, and the currents lower (all else being equal, of course) and thus reduce I^2*R losses. This can be beneficial if this line is being used between an antenna and a transmatch/tuner/coupler, where a relatively high SWR may be expected on the transmission line.

The OP might want to consider a two-coax run of RG-6 cable, for a total line impedance of 150 ohms. Satellite-dish RG-6 is available in both black and white - the white coax might help reduce visibility if it's cable-tied to the metal mast.

Message-ID: <4oidnZUpzevvwlbanZ2dnUVZ_vyinZ2d@bright.net>
Source record: 27571

Dear AI4QJ:

It took me a while to find the time to do so, but I have given the
referenced paper a good look.
If their calculations and data can be believed, their antenna is about
60% of the size of the previous example. However, it is still large when
scaled to HF. What it has going for itself is the possibility of designing
multiple (low Z) resonances at two or more well spaced frequencies. One can
envision radio systems needing that sort of capability. (Beacons, cell
phone systems, GPS systems)
My conclusion - giving the paper all benefits of my doubts - is that
this antenna's performance can be matched by other designs over the HF
frequency bands and do so with significantly less mechanical complexity.
Papers have been written that suggest one may let a wire meander within a
volume using a random-walk and in a few iterations find an antenna that is
as "good" as antennas such as shown in the referenced paper.
Keeping in mind the first rule of HF antennas: virtually everything
"works" Antenna design starts with setting down the desired end result and
the physical/fiscal limitations. The complex interaction of the relevant
parameters gives antenna design (as is also the case with the design of
aircraft, bullets, and many other things) its appeal.
If you do not already have the third edition of my mentor's book
(Antennas by John D. Kraus) I recommend its purchase and study.

Wish that I had better news for you. Antennas are exciting, but not
magic. 73, Mac N8TT

From my first post on the topic:

"If Ed connects parallel line from the centre of the dipole to the hot
and
common terminals of the ATU, there is likely to be common mode current on
the parallel line adjacent to the ATU. If the only connection on the tx
side of the ATU is the coax, then it will also have a common mode current
adjacent to the ATU and near enough to equal to the common mode current
on the other side of the ATU."

Sure, you can fabricate a parallel line from two coaxial lines, it just
has much more loss than a conventional air spaced line... and although it
is short, you intend operating it at extreme VSWR. The shielded twin line
you synthesise does not have any magic properties in supressing or
shielding feed line radiation.

Note that I am avoiding the term balanced line that some have used.
Balance is not forced by line geometry, but is a result of the
environment, so balanced lines are balanced by external factors, not the
line geometry.

Owen

PS: I wonder if you had considered end feeding the Inverted V with the
ATU. IIRC you had a sheet metal roof. You could just fix the tuner to the

roof, connect the ground terminal to the roof sheet, and take a wire from the ATU output terminal to the end of the inverted V (which is a continuous conductor across the apex). This is an unbalanced load connected to an unbalanced output. Is that too easy?

> How this varies with freq. I have no idea.

Theoretically, characteristic impedance does not vary with frequency. But depending upon the quality of the dielectric, it will probably take a downward turn at about 1 GHz. It should hold on the 800MHz frequencies you are mostly interested in for the trunked frequencies.

>
> Have a new scanner that says to use 50 ohm coax.

For receive, the difference bewteen 75 ohm and 50 ohm will be nil.

> input impedance of the scanner ?

Yes ;-) But as you say it hardly matters.

> Why ? (again, receive only)

Mismatches reduce the maximum power available from the signal to your receiver back end. However, in your case the SWR of (25/125 +1)/(1-25/125) =1.5. Thus Vmax/Vmin= 1.5 and the power lost by the mismatch = 20log (1.5) = 3.6dB.

If you were matching 50 ohm to 50 ohms on the other hand, then the power lost would be 20log(1+0)/(1-0) = 20log(1) = 0 power lost.

Compare that against the back end gain specs on your receiver, which may be 10X the 3.6dB(power) value or more, and you can see that the loss of the 75 to 50 ohm mismatch is not significant. Even for transmitting purposes, an

SWR of 1.5 is actually quite good.

The answer is that making the feedline physically symmetrical doesn't make it "act as a balanced feedline". A feedline is balanced and not radiating only when the common mode current is zero, i.e., the currents on the two conductors are equal in magnitude and opposite in phase. Making a line physically symmetrical doesn't guarantee or cause this. Nor, for that matter, does making a line physically asymmetrical (e.g., coax) necessarily cause a line to become unbalance. There's more about this at http://eznec.com/Amateur/Articles/Baluns.pdf.

Message-ID: <13snb9mg6igotd1@corp.supernews.com>
Source record: 27575

Perhaps a little amplification of what Owen has said will help clarify the situation.

Suppose we have a twinlead transmission line, one conductor of which is carrying a current of 2 amps at one point, and the other 3 amps at the same point. For simplicity, we'll assume that the currents are exactly out of phase. The common mode current (as we'll define it*) is 3 - 2 = 1 amp. (We can directly subtract them due to the assumption that they're exactly out of phase; otherwise we'd have to do a vector addition.) So the line will radiate exactly as though there was a single conductor carrying one amp. This is an unbalanced, radiating feedline.

Now let's replace the line with a coax line of the same impedance so it doesn't otherwise alter the system. What we'll find is that the center conductor will carry 2 amps. The inner surface of the outer conductor, which is always forced to be equal and opposite, carries 2 amps of opposite polarity, that is, 2 amps going exactly the opposite direction. On the outside of the shield is one amp, our common mode current. The inner and outer shield currents combine at the cable ends to become 3 amps. This line will also radiate just like a single conductor carrying one amp.

Finally let's look what happens when we use two coax lines with the shields connected but floating. Suppose the 2 amps is on the center of coax A and 3 amps on the center of coax B. On the inside of the coax A shield is 2 amps flowing one way (the direction opposite the current on the center conductor). On the inside of the coax B shield is 3 amps, flowing the other way. What happens at the ends of the shield? At each end, the 2 amps flowing one way will add to the 3 amps the other way (since they're connected at the ends so there's a path from one to the other), resulting in a 1 amp current which flows down the outside of the shield. This radiates just the same as the others, like a one amp current flowing on a single conductor. Using dual coax has accomplished nothing.

The way to prevent the feedline, whatever the type, from radiating, is to force the currents on the two conductors to be equal and opposite. This can be done by making both the antenna and the tuner symmetrical, in which case any of the three lines will be balanced and not radiate. Another way is to use one or more common mode chokes (current baluns) which will also balance any of the three line types. But just changing from one type of line to another doesn't do it.

I've simplified this analysis to deal only with constant currents, such as you'd approximately have with an electrically short transmission line. But the individual currents maintain the same ratio all along

longer lines, so the same result occurs.

(*) Common mode current is sometimes defined as half the vector sum of the two conductor currents, rather than simply the sum as done here. If you use the other definition, you assume that the common mode current is flowing on each of the two conductors to determine the amount of radiation you'll get. The end result is the same either way.

> together, does create a balanced transmission line. . .

There's a semantic problem here. I and many others consider "balanced" to mean non-radiating, which requires that the two conductors carry equal and opposite currents. Others call any physically symmetrical line "balanced". As I explained in another recent posting (and in the article at http://eznec.com/Amateur/Articles/Baluns.pdf), making a line symmetrical doesn't make it balanced -- that is, it doesn't guarantee equal and opposite conductor currents and therefore doesn't guarantee that it won't radiate. A coax line can be balanced and a symmetrical twinlead line can be unbalanced.

Here of course we are talking about a safety ground connection. But for
RF grounding you could you a counterpoise to your antenna. Just a wire
array under the antenna system as used in the western desert in WW2.
That would help to make the performance of your antennas more
predictable at any rate.
Here in NZ I am having ground troubles in a new subdivision. On a heavy
clay soil with a reasonably heavy annual rainfall ~50 inches/year.
The utility company appears to have very badly balanced the 3 phase
underground power phases and it looks like we have quite a high current
circulating between local grounds on our mains earth neutral system.

Result, a lot of rf noise coming up the ground connection and even being radiated into antennas on local AM radio and ham equipment. They have been working on the problem but after 8 months we still have an s6/7 noise level across the HF bands.
We are still on their case however.

Hello Dan,

Can it be that Bob's situation is better with respect to losses?

75 Ohms load in a 50 Ohms system gives reflection coefficient of
(75-50)/(75+50) = 0.2 (voltage or current reflection).

So the power loss in this transition = 0.2^2 = 0.04 (4%, 0.18 dB).

The absolute worst-case situation would be when you have a quarter
wave line between a 50 Ohms source and a 50 Ohms load. The 75 Ohms
quarter wave line with 50 Ohms load will show a real impedance of
75^2/50 = 112.5 Ohm. This results in a reflection coefficient of
0.38, hence a power loss of 0.15 (0.7 dB). Of course when the line is
0.5 lambda long, there will be no additional loss.

Best regards,

Wim

Right now I am looking at modifying a unit that receives 850, 900
frequencies.
What I am curious about is the concept of small antennas only in
reverse.
A small antenna might be a autombile antenna used for AM reception.

So, taking the unit to receive 850, 900 MHz freuquences, how well
would it receive 2.4 GHZ frequences?
It would seem that it would receive 2.4 GHZ well due to the concept of
effective length but I am not sure.

Any comments?

Thanks, Dave

Dave

While it is true that the antenna will be several wavelengths long and will work reasonably well for receiving there are other factors to take into consideration. As frequencies get higher, signal levels are generally at lower levels. There isn't so much atmospheric noise to overcome and at frequencies above VHF, most communications are line of sight.

For this reason transmitter powers are generally much lower and directional antennae are used as the cheapest way of boosting signal strengths. Log periodic and yagi antenna designs are among the best known types of directional antennae, but other designs can be used very effectively.

Your AM automobile antenna receiving pattern will be broken up into a series of lobes due to its being several wavelengths long at 850-900 MHz. The performance in any given direction will be a bit of a lottery. Have a look at the EZNEC program to get some idea of how the transmitting and receiving patterns of antennae change with frequency and multiple wavelengths of antenna.

For all round (omni directional) reception, the height the antenna is mounted is more critical than anything else. Whatever design you decide upon, get your antenna as high as possible and connect it to the receiver using good quality, low loss cable. Satellite cable will do at a pinch. Even a simple dipole antenna mounted vertically and clear of obstructions around 30 feet up should provide a host of signals. The dipole elements only need

to be around 6 inches long. That should give you an idea of what signals are about and you can progress from there.

Mike G0ULI

If it is vertical and omnidirectional, it will probably
become an end-fire antenna at the higher frequencies.
That means it will likely be directional but mostly
in an up direction. The same thing happens when
a 19 inch vertical whip is used on 440 MHz.

If you regularly have need to calculate field strength / power / path loss according to Friis transmission formula, you may find a little calculator I have written to be handy.

The calculator is called FSC (for field strength calculator) and is a Windows application, more specifically it requires the .NET Framework V2 which is installed on most recent computers, or can be downloaded from Microsoft at no charge.

The calculator is described at http://www.vk1od.net/fsc and can be downloaded and used at no charge.

>
> Roy Lewallen, W7EL
>

In the past, I normally have always used a balanced tuner on my balanced antenna systems..... this one under discussion, being one of those SGC antenna couplers, is NOT balanced..... It did not occur to me that the currents through the twin coax feedlines to the balanced antenna would not be equal. So, to make sure I am understanding you correctly, this un-symmetrical current could also occur in open ladder-line?

Obviously the weakness of my antenna knowledge has been exposed. My thanks to Roy, AND to Owen.

Owen, after reading Roy's explanation, I came back to this one
and what you have been saying is now more clear to me.

I will have to check what is available for end feed on the roof,
but it is a completely rubber covered roof and I doubt there is any
convinent way to access a ground. Tnx.

Careful there. A "zero length" (or infinitesimal) dipole (aka a
Hertzian dipole) does not have an isotropic (spherical) pattern. It has
1.64dBi directivity, as I recall.

What about running radials made of lengths of burlar alarm metal tape? A coat of black spray paint will make them nearly invisible on a black roof.

I didn't see your frequency requirements, but I have had excellent results from a Cushcraft R7. I am amazed at just how well it works, even on 75m (by accident!).

I just got my first HDTV. My rabbit ears work just
fine on the HDTV signals. Here in Tyler, TX, I get
analog channels 7, 19, 51, & 56. I now get additional
digital channels 7.1, 7.2, 7.3, 19.1, 19.2, 22.3,
51.1, 51.2, 56.1, & 56.2. Incidentally, 7.1 is VHF
Channel 10.

His definition fits the description of an isotropic antenna. It's not a dipole or any other kind of real antenna, and has a directivity of one by definition.

Most of the discussion here is more esoteric, than practical. You have
an imposed Antenna Requirement, that gives you little wiggle room in
what you can do. I have given you the ideas, that are proven in the
Real World, for installations with similar requirements. As I stated
in my first post, these type systems, ALL preform equally BAD, when
compared to the Antenna Systems, that these type tuners were DESIGNED
to feed. They are intended to feed a Marconi Vertical, with a very
Low Impedance RF Ground. That is where they work BEST. Everything else
will be a poorer situation. How poor, will depend on a BIG pile of
variables, most of which are esoteric in significance, and will
not make a significant difference in actual Practical Performance of the
Station. Again as I stated in my last post, Capitative Coupling to
RF Ground is the BIG Killer, the second largest problem is selecting
antenna length, so as the Natural Impedance of the antenna is NOT
anywhere near a frequency that you need to operate on. All the rest,
is Picking Nits, and can be discussed at infinitum, without changing
the actual performance in any significant way. One of the posters
suggested building an "counterpoise", (God, I hate that Term) RF Ground
from Aluminum Alarm Tape, on the roof, and then feeding what would be

essentially a end feed wire antenna. That would be preferable, IF you could get the Biggies to go along, but that was NOT, part of the original Problem. In the real WORLD, your Comm's are going to depend more on, if the Band is Open, for your Distance, and Frequency, to the destination, than the Antenna design, and if the Band is NOT open, you aren't going to talk, as Ground Wave Comm's are not usually a significant part of HF Communications.

Just a note, for historical purposes. There was a highly modified SEA1612B Tuner that was designed to feed a Balanced Antenna. It was fabricated out of Two, (2) Tuner Boards, using a Common CPU/Sensor System, that determined the configuration of the Switched Elements on one side of the Antenna, and then locked the same configuration on the Second board for the other side. This scheme was developed by Don Hollingsworth Sr. at G&L Marine Radio, in Seattle, Washington, and was deployed in one or two installations of Maritime Mobile Limited Coast Stations. I never did hear just how well they worked.

Ed,

I would consider the following:

Mount the ATU at an accessible place on the masting near the lowest end.
Bond the ATT's ground terminal to the mast.

If there is a lighting protection conductor, steel rain gutter, steel
roof in proximity of the base of the mast, bond the base of the mast to
them also using substantial conductors (>16mm^2).

At the top of the mast, bond one side of the dipole to the mast.

Run an RG213 or better coax from the ATU to the top of the mast, bond the
shield at both ends to the mast. Connect the inner conductor at the top
to the other side of the dipole, and at the bottom to the output terminal
on the ATU. You must treat the ends of the coax to prevent water ingress.
LDF4-50 would be an even better choice because its closed cell bonded
foam dielectric is better protection against water ingress (it also has
lower loss and higher breakdown voltage). I would not use a foil shielded
coax.

Connect the DC / control wires and input coax to the base of the tuner, but route them through a common mode choke. You may well be able to use RG58C/U for the input feed line (depending on length). Wind several turns of the coax and DC / control wires together through a large ferrite toroid (#43 should be fine). Two or three of these chokes should probably be adequate. You may also want one or two chokes where you enter the equipment room.

Treat all connections to prevent corrosion, especially considering dissimilar metals.

There is likely to be common mode current on the feedline / mast above and below the tuner. The chokes reduce the extent of it to minimise the contibution of the feedline to the radiation system / RFI and conversely feed line noise pickup, and act to reduce RF "flowing into the shack".

> off with a single feedline, but I am dubious about the SGC Tech Rep's
> response since he/she does not seem concerned about feedline
> radiation.

You can take measures as above to minimise the downsides of the lack of system symmetry.

SGC have recommended attaching symmetric loads to their assymetric tuners for a long time (they sell tuners, and didn't at the time have a balanced tuner), and hams have proved it "works" whatever that means.

Hello fellow HRO's

I've got a 50ft tower w/ rotor. Been thinking mounting a 2.4 Ghz WiFi antenna on the rotor to see what it picks up in way of WAP / WLAN's

To get around cable loss problem was going to put a USB adapter at antenna then run USB cable up tower. Have tested USB at ~ 5X it's spec'd range but suspect the 60 - 70' run will be way too long.

Anyone know of a way to 'remodulate' so to speak to 802.11 wirelessly link the output from the antenna mounted adapter back to computer?

Thanks for any thoughts

Bob

You can match any thing to a transmitter with a good antenna tuner, the question is the radiation resistance low enough to efficently transfer energy to free space?

When using a G5RV that was close but not touching the branch of tree I got a flat match, could receive well but did not get out worth a damn. Moving the antenna to an area where there were no trees and using 2 30 Rohn telescopic masts as end poles made a big difference, got a flat match, RX and TX were great.

My 2 cents worth on the subject but I as usual someone will say they transmit great with the branchs laying right on the wire.

I agree with the arcing and fire saw that happen when a wet branch connected with a 660 VAC line on a utility pole once.

==========
You might wish to consider a wireless router ,with detachable antenna
instead ,either with a standard antenna ,all in a wx-proof enclosure or
with an external high gain antenna.
The advantage of using a router is using a ethernet (cat5) cable of any
length. You obviously have to strap a 12V-DC power cable to the cat5
cable for 'feeding' the router.
The router produces enough heat to keep itself dry in its wx proof
enclosure.

When using a USB2 wireless adaptor you will need special amplifying 5
metres long cables (I believe up to 3 can be put in series making the
max length approx 15 metres which is short of your 20+ metres
Moreover you would have to wx-proof the joints which contain the amplifiers
When using a USB adapter you might be in a position to fit this device
in the focal point of a satellite dish which with its high gain (but
being directive) would possibly not necessitate installation on top of a
mast , enabling a shorter distance to your 'service point'
Just some ideas ....

> energy to free space?

The radiation resistance is simply an imaginary circuit element whose dissipation represents the energy transferred to free space. So 100% of the energy supplied to the radiation resistance, whatever its value, is transferred to free space -- by definition.

That said, the radiation resistance does play a role in determining what percentage of the power supplied to the antenna is radiated and what percentage is dissipated as heat. The formula is:

Efficiency = Rrad / (Rloss + Rrad)

where Rrad is the radiation resistance and Rloss the loss resistance. It's essential that both values be referred to the same point. So you can see from this simple formula that for a fixed amount of loss, the higher the radiation resistance, the higher the efficiency. But also keep in mind that the signal from a 79% efficient antenna is only 1 dB lower than from a 100% efficient antenna, so there's not much point in worrying about the last few (or, often, many) percent.

The feedpoint impedance, part of which is the radiation resistance, has to be matched in order to get power to it in the first place. And most tuners are efficient only over a limited range of impedances. So very high or low radiation resistance can result in loss in the tuner, reducing your overall efficiency.

> When using a G5RV that was close but not touching the branch of tree I

A good impedance match doesn't tell you anything about the antenna or system efficiency. But on HF if you can hear signals a lot better than they can hear you, it's a sign of poor system (antenna and tuner) efficiency.

> My 2 cents worth on the subject but I as usual someone will say they
> transmit great with the branchs laying right on the wire.

The effect of branches touching the wire depends very strongly on where along the antenna the branches touch relative to the points of highest E field. So two people could have very different results from touching

branches. Also, you could have very different results on different bands
from the same antenna and same branches.

Use ethernet up the tower and PoE (Power over Ethernet). There's lots of
off the shelf solutions here.

RF interference to/from the Ethernet (or USB for that matter) would be
an issue.

You can also do fiber optics (for ethernet, you can pick up
ethernet:fiber media converters surplus quite cheaply.. Then it's just
the fiber cable with connectors already attached, which can be found
fairly inexpensively, if you scrounge. Fiber is cheaper than coax, in
general.)

Or, as someone else suggested, use a second wireless adapter with a
directional antenna to bridge it to your shack. Then all you need up
the tower is DC power.

You might be able to do it with something like a single WRT54, too.

Bit of update

finished the antenna and got it up and running yesterday, the only HF
gear I have ATM is a 27MHz SSB Cb radio (12 watt), got 1.5-1.6/SWR, so I
guess is working ?:-) (lot of thanks for those who helped)

I was lucky to find 2mm(SQ) tinned wire Insulated, I made the resistor
out of 20 x 18k CF 1w resistor soldered in parallel.
my next question is how much power this antenna can or should handle?
I was thinking somewhere around 20 watts ?

We agree at this point. My SWR of 1.5 was calculated by (1 + rho)/(1-rho) = 1.2/.8 = 1.5. Given that the SWR = 1.5 Vmax/Vmin = 1.5. The mismatch produces a reflected to forward voltage "gain" on the transmission line of 1.5 to 1. In dB, this gain is expressed as 10log(Vout/Vin). Since this is a ratio, the impedance cancels, and we know that power is proportional to voltage squared, thus Ploss would be 2 X 10log(Vout/Vin) = 20 log(1.5) = 3.6dB. If this seems like a "lot" when compared to your 0.18dB, intuitively it seems right to me since the impedance mismatch is actually fairly large, i.e the 75 ohm coax has 50% higher characteristic impedance than the 50 ohm load, even though it ultimately does not make a big difference when compared to the gain of the back end of the receiver that converts microvolt signals to millivolt levels.

> So the power loss in this transition = 0.2^2 = 0.04 (4%, 0.18 dB).

If I made a mistake, this would explain why. I need to find a reference that has the derivation showing that rho**2 = power lost. Since rho is unitless and power is in units of watts, it seems unlikley on the face of it unless something is being cancelled out that I am unaware of. If you have such a reference handy, please post it. Otherwise I will try to find it myself. It has been about 40 years since I took my last RF course so maybe you can understand if I am a bit rusty ;-)

I think that, other than resistive losses, the length of a transmission line has absolutely nothing to do with the SWR (and power loss due to mismatch) OTHER THAN the impedance discontinuity of the match at the antenna feedpoint. In the above example I assumed a perfect match and was only considering the mismatch of the load to the characteristic impedance of the coax.

hi Ed

you might try using a plastic mast (pvc or fiberglass) with enought
strength to survive the load and weather thats hollow and try running
laddar line inside

you can use some solid plastic pipe some ham places sell it or
even a short piece ofmetal mast if you can cut a small slot in

the plastic such that it's integraity is good or u can run the
laddar line down the outside of the plastic pipe pprobably easist
and paint it all black w/rf ok paint very hard to see the feed line
then

way back when i spoke to somone that was 'smart' at sgc and they said
using a short piece of laddar line to feed the dipole (as they way i
happened to do mine almost exactly as you described) they said it was
less than ideal but not bad as long as the laddar line was i believe
less than 10??ft long they said the output definately shouldn't
have any balun as far as the coax feeding the tuner?? most
seemed to agree it wasn't needed but i thru one in anyway both on
the roof and in my shack

my set up thou slightly different than yours unscientifically seems to
work very well, i don't have nasty stuff on my coax run to the tuner
my swr even w/a very short dipole is nearly almost always max at 1.2
worst case the tuner tunes in seconds and i've enjoyed some pretty
good fun the total length of my dipole is maybe less than 40ft

is my set up ideal? or good as a beam? i'd guess not but i had co
op board roof constraints as you sorta have so it's best effort
and i've had a blast with it from 160 to 6m

i got a bunch of my ideas for it's actual design and final construction
from my fooling aournd , here in this group , sgc personal I think i
spoke to the original owner once, there manuals and googling

Thanks for all the suggestions

Don't understand the '... second wireless adapter ...' suggestion? where's
it get power?

I've got an EUB-362EXT adapter. (has an SMA connect) Was the longest range
device I could find. Antenna will be connected directly to it, rather than
using the adapter dipole inserted inside a reflector

FWIW - The EUB adapter significantly out-performs a low cost linksys usb
adapter both using their own antenna's. Parked at same location linksys
found 2 WAP's the EUB found 8

Hi Bob

It would seem that Frank's (KN6WH) suggestion about using a Bridge or
Router, or Switch avoids alot of the USB limitations. Have you tried using
a CAT 5 device located at the top of the tower?
I thought the CAT 5 devices were far better than USB for remote WiFi.
But, if you have data / experience that shows otherwise, I'd like to learn
more about why the USB is chosen.

Hello Dan,

To help you a bit: Assume a source with 1Veff EMK and 50 Ohms output impedance.

Calculate the power dissipated in a load of 50 Ohms. When you do this, you will find 5mW dissipated into the load. 0.5Veff will be across the load.

Now, do the same for a 75 Ohms load, you will find 4.8 mW (that is 0.18 dB below 5mW). So 0.2mW (4%) is reflected back to the load. Check you SWR instrument, probably it gives both SWR and reflect power on the scale.

Note that this calculus is for linear systems, hence not valid for most power amplifiers because these want to see a 50 Ohms load, but do not show a 50 Ohm output impedance in general.

Regarding length of transmission lines. When using a 75 Ohms line in a 50 Ohms system, you have two transitions where reflections occurs; at the load and at the source. These reflection will interfere and depending of the amount of wavelength between the load and source, constructive or destructive interference occurs. Search for quarter wave transformer. When you put two, quarter wave transformers (with same cable impedance) behind each other, the input impedance will be equal to the load impedance (assuming loss free cable).

When the VSWR in the cable becomes excessive (high voltage and high current regions), the effective cable loss will increase (with respect to the published values).

Best regards,

Wim

If the source is a signal generator equipped with a
circulator and load resistor, that would be the case.

For more ordinary sources, there are many variables.
It depends upon the phase angle between the forward
wave and reflected wave at the source and upon the
source impedance seen by the reflected wave.

In that case you need 2 routers ,R-1 in top of the mast with a
(sensitive) internal or external antenna having one of its ethernet
ports connected to an ethernet port of the second wireless router R-2
serving as a wireless bridge and fitted lower on the mast ,having a not
so sensitive antenna but sufficient for communication with any wireless
router or adapter inside the house/shack.
R-2 should be set to communicate on an 'extremity' channel say channel
13 ,which will hopefully not be needed by R-1. This to avoid that the 2
routers 'bite' each other .

A (wireless) router is a bi-directional input-output device .
When the wireless side is receiving it passes the information on to the
ethernet port serving as output and vice versa.

Hope the above makes sense

Surely all you need is a wireless card in the pc that you wish to connect to the router on the mast. If you happen to have a router in the house as well it is no different to your next door neighbour having a WiFi network. You just connect to whichever router you wish to.

Jeff

Hi Bob,
I have done something similar to what you want to do. I picked up MFJs yagi
antenna MFJ-1800
http://www.mfjenterprises.com/man/pdf/MFJ-1800.pdf
and a $13.00 wireless USB adapter. I adapted an N connector to the wireless
USB adapter.
(a little troublesome, large connector, small adapter) I then connected the
N connector/adapter assy
to the yagi. I mounted the whole thing in a 4" pvc pipe. I purchased two 15
ft USB male to female cords.
I found I had intermitent performance, The problem was 30 ft of USB cords,
I cut back to one 15ft cord
and the ass'y works wonderfully. I can see over 20 wifi signals from where
I'm at, only 3 to 4 are strong
signals (over 50%, whatever that means). While trying to solve the
intermitent performance I did find
there are cords available with amplifiers built inline to extend the usable
USB cable length. I did not try
these I just moved my yagi. The others are way ahead of my knowledge
regarding the wireless router and
it's operation on top of your tower.
Mike

==========
As long as you use the 2 routers connected with their ethernet ports
,with each router on a different Wifi channel

One outdoor router on top of the mast won't be enough. When that router
receives its WiFi signal from a remote station ,it outputs that signal
to its ethernet port(s) , so in order for the indoor PC with a WiFi
port to receive that signal ,you need a WiFi bridge eg another wireless
router connected piggy-back with the one on top of the mast ; there is
no escape from it.

In the end it will highly likely be easier and more cost-effective to
run an ethernet cat5 cable from the router on top of the mast to the
indoor PC along the router's low voltage power supply cable , of course
unless the router on top of the mast has its own local battery nearby
which is being charged by a local solar panel , doing away with (long)
cables altogether.

Hi Frank

I'd like to learn more about WiFi DX. So, this post is a request for information

If this was *my* project, I'd install a Wireless Bridge at the top of the tower and supply it with both a CAT 5 cable and a pair of wires to power it. I'd also have a Router at the ground for connection to the LAN.
What would be the problem with installing a Wireless Switch atop the tower with it's CAT 5 and power wires to allow the ground based computer with its RJ 45 port to "see" the signals from the nearby wireles sites? Wouldnt that allow using only one CAT 5 device? Then, it is possible to connect to the Internet (thru any WiFi site you are able to receive and enter) with only one Wireless device.
I I thought it was possible to connect to the Internet with only one Wireless device. And, a CAT 5 cable device is far better than a USB cable for long cable runs.

Jerry

if you set up two wireless to ethernet bridges back to back you can use the second to relay the traffic on the "wide area" one back to your shack. (e.g. the "remodulate" function asked for). You could also just use a single 802.11 device up top, configured as an access point in infrastructure mode, with no ethernet connected. It will repeat out all the packets, and, so, with a directional antenna at the shack pointed at your towertop AP you can communicate. However, managing the AP will be a challenge, especially if there's an RFI issue.

Power would be separately supplied, but you can put a small regulated DC supply up at the top. My own preference would be to use a quiet DC/DC converter with wide input range, so you don't care about voltage drop on the wires heading up.

there are some practical details. For one thing, a lot of wireless access points don't provide full control functionality over the wireless port (for security, among other reasons). For instance, changing the RF channel number is trickier "over the air".

The other thing has to do with available data bandwidth.. 802.11 PHY is essentially a half duplex protocol (i.e. it doesn't Tx and Rx at the same time). If you set up two units back to back, you can run the second link on a different channel for your "shack to tower" link, so those packets don't have to go over the air on the "tower top" unit.

Lots of possibilities, lots of ways to do it.

You can also create a "MESH" network where the router acts as an access point relaying data between nodes. I have a Linksys access point that will do it with others of the same model, and the famous Linksys WRTG54-L running one of the Linux distributions for it (for example Tomato) can do it.

Then all you need is a router running a similar system near the base of the tower, and one on top of it.

Using a gain antenna is also possible to increase your range, but you have to be careful about gain. In the U.S. you can increase the output power 10 times (from 100mw EIRP to 1W EIRP) for mobile devices (up to 4W EIRP for directional point to point links).

Here in Israel, there is a limit of 100mW EIRP, no matter what, even for licensed hams (25W limit for satellite use only).

Geoff.

I'd use PowerOverEthernet (PoE).. runs the power up the Cat 5, and it's
already galvanically isolated. Off the shelf adapters to feed the power
in and take it out.

If you want omni for the top of tower, you can put the gain antenna down
at the shack. 10-20dBi is easy to come by, and gives you a factor of
3-10 range improvement.

Usually, WiFi Routers come with firmware, that only allow the RF Port to
communicate with the Ethernet Lan and Wan Ports, and not with other
connected client devices. This can be modified via a Open Source
firmware revision, but is NOT the usual case.
I for one, use a Buffalo AirStation G HP at the top of the tower,
feeding a 24dbi Panel Antenna. It is powered via the extra two Pairs in
the Ethernet cable, via a really nice little 9-18 Vdc Input/5 Vdc Output
Dc/Dc Switching Power Supply. This setup also has a really nice little
Trendnet IP400W Pan/Tilt/Zoom WebCam that is also connected to the Lan
side of the Router, and provides a easy way to picture the neighborhood.
Both devices, when operating, draw about 700ma and the whole system is
powered by a 12Vdc Solar charged 8D Battery, and the Dc/Dc takes care of
the voltage drop encountered in using the 24 Gauge wires in the Ethernet
Cable run of 100 ft.

>scanner) ?

If they advertise/sell it as being acceptable for satellite-dish use,
I'd think it would be electrically fine for scanner applications.
Sat-rated RG6 is normally quad-shielded and has low losses up to above
1 GHz.

Pay plenty of attention to how you attach (crimp, probably) the
connector on the end, and to waterproofing the resulting connection to
the antenna. Water infiltration into the end of a cable is one of the
commoner failure modes.

Ordinary black plastic electrical tape, by itself, isn't really
adequate for the job. I usually use some combination of
self-amalgamating rubber tape, and Coax Seal or a similar putty, to
ensure waterproofing, and an outer layer of black electrical tape to
shield the inner waterproofing layers against sunlight/UV.

Sorry, I don't believe in the tooth fairy, free lunches, or dummy
loads on sticks. Or should I say dummy loads on towers...
>
> Just to make things even, it is my belief that someone, who has the
> respect of most ham's in this group,(including the indomitable
> Richard) has a finger in this pie.

Well, Yoda is pretty good at what he does. But I doubt if
even the force® can save this project.
Like I have said, if I thought it was possible to achieve full
size performance from a shoe box sized jumble of several
hundred feet of thin 22 gauge wire, I would have already built one.
But unfortunately, I have no such delusions of RF grandeur.
BTW, if even both of the Richards, "I'm not sure which one
you consider indomitable", had a finger in the pie, but
the rest of the world refused to stick their finger in the pie,
how would that make things even?
Myself, I have trouble seeing either one of them falling for
this fairy tale of full size antenna performance from a
mini sized dummy load on a stick. Even if it is air cooled.
Does this help clarify my stance on this small sized subject?
I try to avoid any gray areas that might give the impression
that I think this device even has a remote chance of it's
claimed full sized success as a radiator of RF.
But in case some still get confused by what I say, let me
rephrase in a manner that most all will understand.
What a load of horse manure says I...

I wrote some notes on RG6 for transmitting applications at
http://www.vk1od.net/RG6/index.htm .

I know you were intereested in receive only, and a specific brand, but the issues discussed might be of intererest in selection of a cable type and connectors.

I have purchased for very little money two identical VHF TV Yagi-Uda antennas. They have 300 ohm output impedance, 5 elements, wide band.

I am thinking to install both on the mast and connect both to a mixer in order to double the output. I m not an expert in antenna design and therefore I m asking for some clarifications:

1.. If my supposition is correct, at what vertical distance should I install the two antennas to avoid cross interference?
2.. I assume that to double the signal the cable type and length from the two antennas to the mixer has to be the same. Correct?

Thank you very much,

Gene

There are people who will happily believe most anything without any credible evidence. Examples abound - believers in homeopathy, astrology, and alien abductions to name just a very few. Believers in Art's antenna claims are in this category. I'm not.

However, you and W8JI seem to believe that the delay through
a 75m bugcatcher loading coil can be 3 ns. Compared to that
belief, astrology seems pretty logical.

Looks good. And well presented. There is only one small problem
with the analysis.

When the instantaneous energy flows are examined it can be seen
that Prs is not equal to 50 W plus Pref.

Taking just the second example (12.5 ohm load) for illustrative
purposes...

The power dissipated in Rs before the reflection arrives is
Prs.before = 50 + 50cos(2wt) watts

The reflected power at the source is
Pref.s = 18 + 18cos(2wt) watts

But the power dissipated in Rs after the reflection arrives is
Prs.after = 68 + 68cos(2wt-61.9degrees) watts

Prs.after is not Prs.before + Pref, though the averages do sum.

And since the energy flows must be accounted for on a moment by
moment basis (or we violate conservation of energy), it is the
instantaneous energy flows that provide the most detail and
allow us to conclude with certainty that Prs.after is not
Prs.before + Pref.

The same inequality holds for all the examples except those
with Pref equal to 0.

Thus these examples do not demonstrate that the reflected power
is dissipated in the source resistor.

I should have mentioned that there are some energy flows that do
add, as expected.

The energy delivered by the generator to the line (or equivalently,
the energy flowing in the line at the generator end) is the sum
of the forward and reverse energy flows...

Pf.g = 50 + 50cos(2wt)
Pr.g = -18 + 18cos(2wt)
Pline.g = 32 + 68cos(2wt)

And the energy delivered by the source is always equal to the
energy being dissipated in the resistor plus the energy being
delived to the line...

Prs = 68 + 68cos(2wt-61.9degrees)
Rline.g = 32 + 68cos(2wt)

Psource = 100 + 116.6cos(2wt-30.96degrees)

Psource is equal to Prs + Pline.g

So the energy flows that should add up, do add up.

That is irrelevant. The power (irradiance) model
doesn't apply to instantaneous energy and power.
Hecht says as much in "Optics".

Nobody has ever claimed that the energy/power
analysis applies to instantaneous values. The
energy/power values are all based on RMS voltages
and currents. There is no such thing as an
instantaneous RMS value.

There are no reflections at the source so the reflected
energy flows through the source resistor. There is no
interference to redistribute any energy. There is no
other place for the reflected energy to go.

Placing a wireless router at the top of the tower is not a solution. I am
assuming of course that the OP wants to connect to other wireless routers. I
wanted to do something like this and all the computer tech people I asked
said wireless routers dont talk to each other wirelessly.

Amateur Radio License Exam Preparation Software
Getting your Amateur Radio License has never been easier. Effective February 23, 2007 the FCC removed the Morse Code requirements for all Amateur Radio License Classes . Since that date, applicants for a Technician, General or Extra Class Amateur Radio License no longer have to demonstrate proficiency in Morse Code. You just have to pass the applicable written examination.

That's where we come in. Our amateur radio license exam preparation software serves as a training aid to help amateurs and prospective amateurs pass the Volunteer Examiner Coordinator's (VEC's) administered exam. When you can consistently pass the exams given by our exam preparation software, you will almost certainly pass an actual Volunteer Examiner Coordinator's (VEC's) administered exam.

Our amateur radio license exam preparation software uses the latest officially released Volunteer Examiner Coordinator's (VEC's) approved question pools. The program breaks the test into different sub-element. Integrated into the software are illustrations and Part 97 rules pertaining to the current question. The program tracks the progress of the tests taken. Once you have mastered each sub-element you are ready for the officially administered exam.

Wait a little while and the FCC will grant us a single block license as they did in the Seventies for CB licensees. Then you can make up your own callsign and have at it. This is how dimly we are viewed by the powers-that-be.

Hi Jimmie

I am not experienced enough to contradict computer techs. But, I have used a *CAT 5 connected Wireless Bridge* to connect my computer to the Internet by wirelessly connecting to a distant Wireless Router. Maybe I'm using the wrong terminology. But, I want to indicate to the OP that using CAT 5 rather than USB can allow the "wireless device" to be located far away from the computer.

Are you saying that conservation of energy does NOT apply to
instantaneous values?

> The
> energy/power values are all based on RMS voltages
> and currents. There is no such thing as an
> instantaneous RMS value.

I understand the analysis technique you are proposing. That
it leads to the wrong conclusion can be easily seen when the
instantaneous energy flows are studied. This merely demonstrates
that the analysis technique has its limitations.

The bottom line remains that the reflected energy is not
dissipated in the source resistor, even for the special cases
under discussion.

That is the conundrum, isn't it?

And yet the analysis of instantaneous energy flows definitely
shows that the reflected energy is not the energy being dissipated
in the source resistor.

Encountering this conundrum, and not wanting to give up on
conservation of energy, is what helped me form my views on
the nature of reflected energy.

Art did ship me one of his antennas a week or two back... I have it in my shop...
I will indeed put this interesting antenna to an objective and thorough testing with a full report here... I am always excited to learn something new...

It is 19F outside this morning and blowing hard, with wind and snow forecast through the week and into the weekend, and I am unlikely to climb the big tower in this...
I will attempt within a week to put it on a small <50'> tower I have attached to my shop and get some baseline impedence and field strength measurements... Then as soon as the weather allows I will move it to the big tower for a good test against my full size antennas...

I am sorry to have to put this off a bit, but given the weather and that my family is hurting at the moment my free time is limited...

> said wireless routers dont talk to each other wirelessly.
==========
Correct ! and because of that you would need a wireless bridge
operating on a different RF channel than the wireless router which
'senses the neighbourhood'. To prevent clashes the wireless bridge
should operate on a channel not used by the other wireless router.
All of this refers to standard consumer type of routers.

Whatever , a single router connected by cat5 cable to the monitoring PC
indoors seems to be the most cost effective solution.
Cat5 can be laid underground when run in plastic water pipe ,together
with the power supply wiring for the router.

For the past 16 years our satellite dish is located away from the house.
Its 75 Ohms coax runs through 20mm OD polyethylene water pipe (blue
colour , as is nowadays standard in Europe)

Where the cable(s) leave the water pipe ,the pipe opening should point
downwards such that water ingress is prevented. The exits should be
left open to prevent condensation inside the water pipe.
I have never had a problem with any type of cable when run underground
this way.

How do you justify this conclusion? It seems to me that until the reflection arrives, the source will have a load of Rs = 50 ohms plus line = 50 ohms for a total of 100 ohms. Prs.before = 50 watts.

There would be no reflected power at the source until the reflection returns, making the following statements incorrect.

Rs is shown as a resistance on only one side of the line. It would simplify and focus the discussion if Rs were broken into two resistors, each placed on one side of the source to make the circuit balanced.

> How do you justify this conclusion? It seems to me that until the reflection arrives,
the source will have a load of Rs = 50 ohms plus line = 50 ohms for a total of 100 ohms.
 Prs.before = 50 watts.

The voltage on Rs, before the reflection returns is
Vrs(t) = 70.7cos(wt)
Prs(t) = Vrs(t)**2/50
= 50 + 50cos(2wt)

Prs.before.average = average(Prs(t))
= 50
since the average of cos is 0.

My apologies for leaving out the "(t)" everywhere which would have
made it clearer.

> There would be no reflected power at the source until the reflection returns, making the
following statements incorrect.

I should have been more clear. The below applies after the reflected
wave returns.
And I should have included the "(t)" for greater clarity.

I am not sure how this would help. It would make the arithmetic
somewhat more
complex.

What is interesting is that in the formula for power
dissipated in the source resistor, the 50 watts is
an average power. It is an invalid procedure to try
to add instantaneous power to an average power.

> Do you also use only the RMS phase and RMS interference to come up with
> your RMS answers?

I didn't say anything about "RMS phase and RMS interference".
The phase angle used in Hecht's irradiance equation is the
phase between the electric fields of the two waves. The
magnitude of the interference is an average magnitude based
on the RMS values of voltage and current.

I do exactly what Eugene Hecht did in "Optics". He said:

"Furthermore, since the power
arriving cannot be measured instantaneously, the detector
must integrate the energy flux over some finite time, 'T'.
If the quantity to be measured is the net energy per unit
area received, it depends on 'T' and is therefore of limited
utility. If however, the 'T' is now divided out, a highly
practical quantity results, one that corresponds to the
average energy per unit area per unit time, namely 'I'."
'I' is the irradiance (*AVERAGE* power density).

i.e. The irradiance/interference equation does not work
for instantaneous powers which are "of limited utility".

Of course not. I am saying that the 50 watts in the
source resistor power equation is an average power.
It is invalid to try to add instantaneous power to
an average power, as you tried to do.

>> The

The proposed analysis technique is a tool. Trying to apply
that tool to instantaneous powers is like trying to use a
DC ohm-meter to measure the feedpoint impedance of an antenna.
Only a fool would attempt such a thing.

> The bottom line remains that the reflected energy is not
> dissipated in the source resistor, even for the special cases
> under discussion.

Saying it doesn't make it so, Keith. There is nothing to
keep the reflected energy from being dissipated in the
source resistor.

If the reflected energy is not dissipated in the source
resistor, where does it go? Please be specific because it
is obvious to me that there is nowhere else for it to go
in the special zero interference case presented.

Here are some of your choices:

1. Reflected energy flows through the resistor and into
the ground without being dissipated.

2. The 50 ohm resistor re-reflects the reflected energy
back toward the load. (Please explain how a 50 ohm load
on 50 ohm coax can cause a reflection.)

3. There's no such thing as reflected energy.

4. Reflected waves exist without energy.

5. _____.

Your analysis seems to be flawed. You are adding average
power terms to instantaneous power terms which is mixing
apples and oranges.

Gentlemen;

What I was taught long ago was that the phenomenon that we call reflected energy is radiated on the return. That portion of energy that is not radiated is re-reflected and is radiated. This continues until the level of energy no longer supports radiation. Resistance also dissipates a portion of the transmitted energy. That resistance includes the resistor under discussion above and that resistance found in the coax conductors.

Of course my Elmer could have been wrong.

Depends on the particular wireless box. Some D-Link boxes, for
instance, have a point-to-point or point-to-multi-point capability.
```

Also, if the box at the top of the tower is an access point in infrastructure mode, it essentially repeats packets that it receives. This is so that two computers that are connected to the AP can talk to each other.

> Of course my Elmer could have been wrong.

Your Elmer was parroting the party line which is:
Any reflected energy dissipated in the source was
never sourced in the first place. Therefore,
at the source (by convention and by definition):

Sourced power = forward power - reflected power

If that is true, it follows that all reflected power
must necessarily be re-reflected back toward the load
(even if, in the process, it violates the laws of physics
governing the reflection model). Since contradictions
don't exist in reality, there must be another explanation.

An antenna tuner which achieves a Z0-match allows no
reflected energy to be incident upon the source so, for
that most common configuration, all is well and your
Elmer was right about those Z0-matched systems.

However, when reflected energy is allowed to reach
the source, it is naive to think that none of that
reflected energy is ever dissipated in the source
resistance when the source resistance is dissipative
as it is in the example under discussion here.

Both of the following assertions are false:
1. Reflected energy is never dissipated in the source.
2. Reflected energy is always dissipated in the source.
Most assertions containing the words "always" and "never"
are false.

There will be three more parts on this topic published
on my web page. The top page will be on the subject
of interference which will explain how reflected energy
can be redistributed back toward the load after not
being re-reflected.

> apples and oranges.

I do not think that is the case.

The expression for instantaneous power in Rs before the reflection
(or, if you prefer, when a 50 ohm load is used), is

Prs(t) = 50 + 50cos(2wt)

It is trivial to compute the average of this since the average
of a sine wave is 0, but that does not make the expression the
sum of an average and an instantaneous power.

As an exercise, compute the power in a 50 ohm resistor that has
a 100 volt sine wave across at, that is
V(t) = 100 cos(wt)

You will find the result is of the form shown above.

So when you add the instantaneous power in Rs before the reflection
arrives with the instantaneous power from the reflection it will
not sum to the instantaneous power dissipated in Rs after the
reflection returns.

Thus conveniently showing that for this example, the reflected
power is not dissipated in Rs.

You used your tool to attempt to show that the reflected power
is dissipated in Rs.

I did a finer grained analysis using instantaneous power to show
that it is not.

The use of averages in analysis can be misleading.

Now you have got the issue. Since the reflected power is
not dissipated in Rs, the answer must be one of 1 to 5.

5. is probably the best choice.

And that is why it became necessary to rethink the nature
of energy in reflected waves.

> power is not dissipated in Rs.

The *average* reflected power is certainly dissipated in Rs
because there is nowhere else for it to go. Your instantaneous
power, according to Eugene Hecht, is "of limited utility" which
you have proved with your straw man assertion above.

I have made no assertions about instantaneous power. All of
my assertions have been about average power and you have proved
none of my assertions about average power to be false.

Here is what you are doing:
Cecil: My GMC pickup is white.
Keith: No, your GMC pickup has black tires.

Your diversions are obvious. Instantaneous power is irrelevant
to my assertions.

Keith Dysart wrote:
> You used your tool to attempt to show that the reflected power
> is dissipated in Rs.

The tool proves that the reflected average power is dissipated
in Rs because it has no where else to go. If instantaneous
reflected power were relevant, why don't we read about it in
any of the technical textbooks under the wave reflection model?

> I did a finer grained analysis using instantaneous power to show
> that it is not.

My tool is known not to work for instantaneous power and
was never intended to work for instantaneous power. So your
argument is just a straw man diversion. Eugene Hecht explains
why average power density (irradiance) must used instead of
instantaneous power.

"Furthermore, since the power
arriving cannot be measured instantaneously, the detector
must integrate the energy flux over some finite time, 'T'.
If the quantity to be measured is the net energy per unit
area received, it depends on 'T' and is therefore of limited
utility. If however, the 'T' is now divided out, a highly
practical quantity results, one that corresponds to the
average energy per unit area per unit time, namely 'I'."
'I' is the irradiance (*AVERAGE* power density).

> The use of averages in analysis can be misleading.

The misuse of a tool, designed to be used only with
averages, can be even more misleading. When you measure
an open-circuit using a DC ohm-meter on a dipole, are
you really going to argue that the DC ohm-meter is not
working properly? That's exactly what you are arguing here.
When one misuses a tool, as you are doing, one will get
invalid results. There's no mystery about that at all.

You are saying that the energy model, designed to be
used with average powers, does not work for instantaneous
values. When you try to use it for instantaneous values,
you are committing a well understood error. Why do you
insist on committing that error?

>> 5. _____.
>
> Now you have got the issue. Since the reflected power is

Until you fill in the blank for number 5, you are just
firing blanks. :-) Exactly what laws of physics are you
intending to violate with your explanation?

> And that is why it became necessary to rethink the nature
> of energy in reflected waves.

Nope, it's not. Reflected waves obey the laws of superposition
and reflection physics. That's all you need to understand.
Now new laws of physics or logical diversions required.

Hecht seems to have sufficient reputation that I trust that he made
this statement in the context of optics and not in the context of
electrical circuits.

> I have made no assertions about instantaneous power. All of

EM waves are EM waves, Keith, no matter what the frequency.
EM waves all obey the laws of reflection physics, superposition,
and conservation of energy principle. If you want to prove those
laws to be invalid and replace them with ones of your own design,
be our guest.

> But analysis using instantaneous power reveals a different
> answer. Which is more likely to be correct?

Analysis using an MFJ-259B on an antenna system reveals a
different impedance than is indicated by a DC ohm-meter.
So what? You used an average power tool, known to be
invalid for instantaneous powers, to incorrectly analyze
instantaneous powers. You are the one who made the error
- not the model. Your error was the (deliberate?) misuse
of the tool in order to try to create your straw man.

Using the power equation, derived from RMS values of
voltage, on instantaneous powers is an invalid thing
to do and will give known erroneous results which are
not the fault of the average power model. The fault is
in the *misuse* of the average power model.

We have already laid your straw man argument to rest
when we discussed the power in standing waves.

1. There is non-zero instantaneous power in standing waves.
2. There is zero average power in standing waves.

Does statement 1 contradict statement 2? Of course not.
They are both true. The same holds true for the present
discussion.

I have a probable explanation for your calculations. I
set the example up such that the average interference
is zero inside the source. It is entirely possible that
localized interference exists within each cycle such
that there is destructive interference for part of the
cycle and constructive interference in another part of
the cycle. In fact, based on the conservation of energy
principle, I am willing to state that is a fact and the
destructive interference magnitude exactly equals the

constructive interference magnitude for each cycle.

I highly recommend that you decouple the feedline with a current balun (common mode choke). Better yet would be two, spaced about a quarter wavelength apart. Small antennas can be made to look a lot better than they really are if the feedline is allowed to become part of the radiating antenna system, so unless the feedline is decoupled well, any measurements you make will be subject to speculation as to whether the radiation was from the antenna or the feedline.

On Mar 5, 8:06 am, Cecil Moore <nos...@w5dxp.com> wrote:
...blah, blah...

So consider the case of a section of lossless uniform transmission line of characteristic impedance R0, which I write as R instead of Z since it of course must be real-valued, connected between two sources S1 at end 1 and S2 at end 2. These sources each have source impedance R0: they are perfectly matched to the characteristic impedance of the line. The line is long enough that we can observe any standing waves that may be on it. (For believers in directional couplers, that can be short indeed, but it does not need to be short.) Source S1 is set to output a sinusoidal signal of amplitude A1 into a matched load, on frequency f1. Similarly S2 outputs a sinusoidal signal A2 into a matched load at frequency f2, which is distinct from f1.

It is easy to show mathematically, and to measure in practice, that the amplitude of the frequency f1 is constant along the line, and similarly that the amplitude of the frequency f2 is constant along the line. That is to say, there is no standing wave at either frequency. Energy at f1 travels on the line only in the direction from S1 to S2, and vice-versa for f2.

That says to me that the energy on the line at f1 is absorbed entirely by source S2, and the energy at f2 is absorbed entirely by S1, with no reflection at the boundaries between S1 and the line, and the line and S2.

At this point, I leave it as an exercise for the reader to interpret or explain exactly what is meant by "absorbed by." This may involve understanding that in a Thevenin or Norton simple model of each source, the energy delivered by the voltage or current source at any moment in time may not equal that which it would deliver into a matched load at the same point in the cycle...

Cheers,
Tom

It would also be interesting to use a simple current probe to sweep
along the feedline, and see what sorts of currents might be flowing
along the outside of the feedline, both with and without a good
common-mode choke or two in the feedline.

2850. antenna impedance matching on small TX

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-05 21:19:50 UTC
From: Marcus Tait <marcus_taitNOSPAM@hotmail.com>
Message-ID: <q5adnZ2GDavrk1LanZ2dnUVZ8vudnZ2d@bt.com>
Source record: 27422

I have been designing a small transmitter on 400MHz. The output from the rf amp is a parallel LC tank and between the collecter and +V. When measuring the output on a specturm analyser i can get most output when centre tapped on the inductor. The output must then be matched to 50ohm as the spectrum analysers input is 50ohm. The anatenna for this transmitter is just going to be a 1/4 wave piece of wire. My question is that as i dont need to send the signal down any 50ohm cable could i just connect the antenna at the collector rather than tapping onto the inductor and then adjust the length of the antenna to increase its inpedance to match the output inpedance of the transmitter.

What you have described is a system with two sources which
are incapable of interfering with each other because they
are not coherent. Note that this example bears zero resemblance
to a system where the sources are coherent, i.e. frequency-
locked and phase-locked and therefore, capable of interference.

Obviously true for non-coherent sources.

Obviously true for non-coherent sources.

Unfortunately, "non-coherent sources" is not the subject of
this discussion. The rules change between non-coherent, non-inter-
fering sources and coherent, interfering sources. I suggest you
reference the "Interference" chapter in "Optics", by Hecht.

Cecil,

It is likely that all of these interference-related items you like to
quote from Hecht are cast in an environment of lossless optical
components. The characteristic impedance is set by the index of
refraction of the various layers, but none of the optical layers have
any absorption.

Soooo, how does any of this optical stuff extend to making arguments
about the absorption or re-reflection of energy in the source resistor
for the HF case?

The laws of physics may be inviolate, but it is not quite so clear that
your derived and extended models share the same characteristic.

My experience based opinion based on Amateur TV work from many years
back says that a half wave dipole with a link coupling (not critical)
to that inductor will spare you the agony of trying to find a ground
to serve the bottom end of that 1/4 wave wire.

Don't overlook the old practice of using a micro ammeter (or modern
equivalent) with a germanium diode across an identical dipole as a
field strength meter. Best keep the diode shorted when not in use to
protect the meter!

When two equal amplitude coherent signals are superposed,
the resulting power density can be four times the power
density of one of the single waves due to constructive
interference.

That is not true for two equal amplitude non-coherent
waves of different frequencies. The interference term
averages out to zero so there are no bright rings and
dark rings.

I'm surprised you don't know that.

>

I agree. I think it's quite possible that even a decoupled feedline
will add enough radiation to make the antenna noticeably better
than it really is.
I'd prefer to see the source mounted *at* the antenna to make it
a decent comparison.
One problem with the decoupling that I can see, is if it's used on
160m, a quarter wave is about 125-130 feet plus or minus...
So even if you stack two chokes or baluns a quarter wave apart,
I can see the feedline noticeably radiating above the lower choke.
Of course, this condition will exist for all types of antennas,
but on the other hand, most antennas will be radiating quite
a bit more from the antenna, vs the feedline.
So the difference between the two sources are much larger,
and the feedline radiation is more likely to be swamped and
made a non issue as far as the total radiation.
But with such an inefficient small antenna, the feedline
radiation will be a much larger part of the total radiation.
My guess on the performance? Probably about the
same as the usual Isotron antenna used on 160m.
And even in the case of the Isotron, I bet a good portion of
the radiation is actually from the feedline.
I don't recall ever seeing any documentation of the Isotron
that recommended decoupling the feedline.
I don't have to stretch my mind to far to wonder why... :/
To quiet the naysayers, "like me", I'd mount a radio directly
to the base of the antenna with a coax union and

do FS tests at certain distances, and then likewise
with the full size antennas.
That would cure the feedline issue real fast.. lol..
Course, that may be more work than Denny wants to
take on..
You could compare it to a mobile set up though, and
keep things on the ground level for ease of testing.
I bet my mobile antenna would whip that thing.
It should, being it's bigger and has more efficient loading.
MK

Yes, yes, you've posted all that a billion times before in this NG.
Now, exactly what part of "linear system" do you fail to understand?

(I might also ask why you're going to so much trouble to be
disagreeable with something that agrees with what you were
posting...but I think I already know the answer to that one.)

And that would be relevant in what manner? Does Hecht discuss interference at flat black interfaces?

Nobody is questioning the laws of physics or Hecht's writings. Many are questioning your extensions to your own models. Name-dropping and invoking the sacred laws of physics do not automatically validate your models.

Did you ever wonder why all of the basic phenomena, both optical and RF, were known to the "ancients", yet you are the first one to pull everything together in this miraculous new version of a reflection model?

I am the one quoting the wisdom of those ancients
which seems to have somehow fallen by the wayside
and been replaced by some pseudo scientific religion.
What is it about the conservation of energy principle
that you disagree with? What is it about the wave
reflection model that you disagree with? What is it
about the principle of superposition that you disagree
with?

I would take a look at how remote garage door openers are configured. They
operate in roughly your frequency range. Mine has a range of about 100 feet.
A 1/4 wave antenna has an input impedance of 37 Ohms, but I suspect you will
not want to do that.

For the equation Vrs(t) = 70.7cos(wt), are you finding the 70.7 from sqrt(50^2 + 50^2)?

If so, how do you justify that proceedure before the reflection returns? I think the voltage across Rs is 50v until the reflection returns. I also think the current would be 1 amp, for power of 50w, until the reflection returns.

Well, as drawn, the circuit is unbalanced. Reflections are about time and distance traveled during that time, so we really don't know where the far center point is located for finding instantaneous values. We are making an assumption that the length of the source and resistor rs is zero which is OK, but we need to be aware that we are making that assumption. By splitting the resistor into two parts, and then adding them together to make

the calculations, we can see that a balanced circuit is intended, but the source resistors are combined for ease of calculation.

```

> For the equation Vrs(t) = 70.7cos(wt), are you finding the 70.7 from sqrt(50^2 + 50^2)?

No. Cecil's circuit has a 100 V RMS source. For this source

Vs(t) = 141.4 cos(wt)

Before the reflection returns, the line acts as 50 ohms. This, in
series with
the 50 source resistor means that Vs(t)/2 is across Rs and Vs(t)/2
appears
across the line.

Vrs(t) = Vf.g(t) = Vs(t)/2 = 70.7 cos(wt)

The power dissipated in the resistor is

Prs(t) = Vrs(t)**2 / 50
= ((70.7 * 70.7) / 50) * cos(wt) * cos(wt)
= 100 * 0.5 * (cos(wt+wt) + cos(wt-wt))
= 50 (cos(2wt) + 1)
= 50 cos(2wt) + 50

> If so, how do you justify that proceedure before the reflection returns? I think the voltage across Rs is 50v until the reflection returns. I also think the current would be 1 amp, for power of 50w, until the reflection returns.

That is the average power. But since the voltage is a sinusoid, the
instantaneous power as a function of time is
Prs(t) = 50 + 50 cos(2wt)
which does average to 50 W, thus agreeing with your calculations.

We are making an assumption that the length of the source and resistor rs is zero which is OK, but we need to be aware that we are making that assumption.

I find it valuable to understand how such an ideal circuit would
operate, then
extend the solution if necessary.

In practice, many circuits are small compared to the wavelength and
these assumptions
do not materially affect the answer.

Of course, it is important to know when they do, at which time more
complex analysis
becomes necessary.

Thanks Keith. I see what you are doing now, although I still don't understand your logic in faulting Cecil on the instantaneous values. I agree with you that the instantaneous values can be tracked, but don't see a fault in Cecil's presentation.

Roy and I went around a few times on whether the source reflects in a case like this. The source reflection controls whether the 50 ohm source resistor acts like 50 ohms to the reflected wave, or acts like a short circuit in parallel with the 50 ohm source resistor.

Unless this antenna is itself balanced, most likely for best efficiency when operating in this configuration there would need to be a conductor running from the elevated tx chassis to a good r-f ground of some kind, either buried in the earth or in the form of a counterpoise. Radiation from that "ground" conductor could be many times greater than from what is considered to be the antenna -- even though no feedline is present..

This is a common configuration used for so-called Part 15 AM installations to get greater groundwave coverage from the 100 mW tx input power allowed under FCC Part 15.219, by ignoring the 3-meter limit on the length of the radiating structure given there.

RF

I made no assertions about instantaneous power at all and
have added a note in my article to that effect. My assertions
about instantaneous power cannot possibly be wrong because
I didn't make any. :-) Nothing in my article applies to or
is concerned with instantaneous power.

For the power density/irradiance/interference equation to
be applicable, certain conditions must be met. One of those
conditions is that all component powers must be *average*
powers resembling power density/irradiance from optics.
Another condition is that the phase angle between the two
waves being superposed must be constant and therefore the
two associated waves must be coherent (phase-locked) with
each other.

> Roy and I went around a few times on whether the source reflects
> in a case like this. The source reflection controls whether the
> 50 ohm source resistor acts like 50 ohms to the reflected wave,
> or acts like a short circuit in parallel with the 50 ohm source
> resistor.

What Roy (and others) are missing is that there is more than
one mechanism in physics that can cause a redistribution of
reflected energy back toward the load. An ordinary reflection
is not the only cause. In a one-dimensional environment,
e.g. a transmission line, there is an additional mechanism
present that can redirect and redistribute the reflected
energy back toward the load.

1. Reflection - what happens when a *single wave* encounters
an impedance discontinuity. Some (or all) of the reflected
energy reverses direction.

2. Wave interaction - what happens when *two waves* superpose,
interact, AND effect a redistribution of their energy components
as described on the FSU web page at:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

"... when two waves of equal amplitude and wavelength that
are 180-degrees ... out of phase with each other meet, they
are not actually annihilated, ... All of the photon energy
present in these waves must somehow be recovered or
redistributed in a new direction, according to the law of
energy conservation ... Instead, upon meeting, the photons
are redistributed to regions that permit constructive
interference, so the effect should be considered as a
redistribution of light waves and photon energy ..."

In the simple ideal voltage source described in my article,
there are no reflections because the source resistance equals
the characteristic impedance of the transmission line.

In Part 1 of the article, there is also no wave interaction
because the forward wave and reflected wave are 90 degrees
out of phase. So for that special case, none of the reflected
energy is redistributed back toward the load. Therefore, for
that special case, all of the reflected energy is dissipated
in the source resistor because all conditions for a redistribution
of the reflected energy have been eliminated.

In the special case described in Part 1, because of the 90
degree phase difference, the forward wave and reflected
wave are completely independent of each other almost as if
they were not coherent. The result in that special case is
that the power components can simply be added because in
that special case, (V1^2 + V2^2) = (V1 + V2)^2, something
that is obviously NOT true in the general case.

Part 2 of the article will describe what happens when
the forward wave and reflected wave interact at the source
resistor and effect a redistribution of reflected energy
back toward the load *even when there are no reflections*.
This is the key concept, understood for many decades in the
field of optical physics, that most RF people seem to be
missing.

But if the major radiation is from the feedline, that will mean the
antenna won't work as it is supposed to.

Since this is voodoo antennaland stuff, the antenna needs to be tested
as Art would suggest, not as we might like. And since most of the chaps
here are a lot smarter than me, I suspect everyone knows that his
antenna just might need that feedline radiation in order to work "properly".

Now after the initial tests in whatever manner Art dictates, *then* the
feedline should be isolated to determine where the major radiation is
coming from.

At that point, your source at the antenna method is the ticket. That
would remove feedline effects altogether.

Is this test going to be written up somewhere? What is the test protocol?

[snip]
> Thanks Keith. I see what you are doing now, although I still don't understand your logic in faulting Cecil on the instantaneous values. I agree with you that the instantaneous values can be tracked, but don't see a fault in Cecil's presentation.

For the special situation described in
http://www.w5dxp.com/nointfr.htm
Cecil is attempting to show that the reflected energy is dissipated in the source resistor.

The logic he employs is:
- before the reflection arrives back at the generator, the source resistor
is dissipating X watts.
- the reflected wave has an energy flow of Y watts.
- after the reflection arrives back at the generator, the source resistor
is dissipating Z watts.
- since Z is equal to X + Y, the energy in the reflected wave is being dissipated in the source resistor.

In other words, since the dissipation in the source resistor increases by the same amount as the power in the reflected wave, the energy in the reflected wave must be being dissipated in the source resistor.

Cecil analyzes the circuit for a number of load resistances and suggests
that the equality holds for any load resistance.

For example, with a load resistance of 12.5 ohms, the original dissipation
in the source resistor is 50 W which increases to 68 W when the 18 W reflected wave arrives back at the generator. That is, X = 50, Y = 18 and Z = 68, so Z is equal to X + Y.

Cecil does all of this analysis using average powers.

But we know that the power dissipation varies as a function of time and
that the power in the reflected wave is a function of time. It is my contention that if it is the energy in the reflected wave that is increasing the dissipation in the source resistor, the dissipation in source resistor should occur at the same time that the reflected wave delivers the energy.

In other words, not only should Z.average = X.average + Y.average,
but Z.instantaneous should equal X.instantaneous + Y.instantaneous
for if the dissipation in the source resistor is not tracking the
energy in the reflected wave, it can not be the energy in the
reflected wave that is heating the resistor.

So using the same 12.5 ohm example,
X.inst = 50 + 50 cos(2wt)
Y.inst = 18 + 18 cos(2wt)
X.inst + Y.inst = 68 + 68 cos(2wt)
but
Z.inst = 68 + 68 cos(2wt - 61.9degrees)

So Z.inst is not equal to Y.inst + X.inst.

This means that the dissipation in the resistor is not happening
at the same time as the energy is being delivered by the reflected
wave, which must mean that it is not the energy from the reflected
wave that is heating the source resistor.

So while analyzing average power dissipations suggests that the
energy from the reflected wave is dissipated in the source resistor,
analysis of the instantaneous power shows that it is not.

I'm working on a project that requires measuring of impedance on a coax antenna feed: resistive, reactive components. Ideally I will need a plus/zero/minus voltage for reactive direction/magnitude.

The absolute value of the reactance is not of prime concern (will drive servo motors, but I need to know capacitive or inductive, and when it is at zero. I have serveral circuits to accomplish this, but they are quite involved. The object of this project is not to design a new Antenna Analyzer, but it is a component, that I would like to make as simple as possible, with accomplishing the stated goals.

I would appreciate any references/articles/links/ideas that you may know of.

Thanks,

Keith Dysart wrote:
> Cecil does all of this analysis using average powers.

That's because the power density/irradiance/interference equation only works for average powers. One condition for valid use of that equation is that the powers must have been averaged over one complete cycle and usually over many, many cycles. How many cycles does it take for a bright interference ring to register on the human retina?

My example is set up such that the average interference is zero over each complete cycle. I cannot think of a way to eliminate interference internal to a cycle. Both destructive and constructive interference occur during a cycle, which is what you are seeing, but interference averages out to zero over each complete cycle.

Destructive interference from one part of the cycle is being delivered as constructive interference in another part of the cycle. That is completely normal.

The same thing happens with an ideal standing wave. The average power in a standing wave equals zero although some instantaneous power can be calculated as existing in the standing wave. You have discovered why Eugene Hecht says that instantaneous power is "of limited utility".

In fact, what we are dealing with in the example is a standing wave because the forward wave and reflected wave are flowing in opposite directions through the source resistor. I hope your math took that into account.

> This means that the dissipation in the resistor is not happening
> at the same time as the energy is being delivered by the reflected

All it means is that there must be some localized interference during each cycle for which you have failed to account. In other words, you are superposing powers which is a

known invalid thing to do when interference is present.

Hard to follow this long sentence/paragraph. The dissipation in the source resistor should be the sum of instantaneous energy flows from both source(forward) and reflected energy flows. We would not expect that the instantaneous energy flow would be equal from both source and reflection because of the sine wave nature of the energy flow.

I think you are mixing average energy flow (the 50 and 18 watts) with instantaneous flow (50 cos(2wt) and 18 cos(2wt)).

I think Z.inst = x.inst + y.inst = 50 cos(2wt) + 18 cos(2wt). The two energy components arrive 90 degrees out of phase (in this example) so we should write z.inst = 50 cos(2wt) + 18 cos(2wt + 90).

The key question: Is the square of the sum of the
two voltages equal to the sum of the squares of
the two voltages? If yes, there is no interference
and it is valid to add the powers directly as
Keith has done.

If no, interference exists and it is *INVALID* to
add the powers directly as Keith has done. Every
EE was warned about superposing powers at the
sophomore level if not before. This is why.

So what we need to know is:

Is [Vfor(t) + Vref(t)]^2 equal to
Vfor(t)^2 + Vref(t)^2 ???

Does [70.7v*cos(wt) + 42.4v*cos(wt+90)]^2 equal
[70.7v*cos(wt)]^2 + [42.4v*cos(wt+90)]^2 ???

Is 2[70.7v*cos(wt)*42.4v*cos(wt+90)] always zero???

The answer is obviously 'NO' so Keith's direct addition
of powers, i.e. superposition of powers, is invalid as
it always is when interference is present.

When the interference term is properly taken into
account, the instantaneous dissipation in the source
resistor will no doubt equal the dissipation from
the forward wave plus the dissipation from the
reflected wave plus the interference term which is
minus for destructive interference and plus for
constructive interference. The interference will
average out to zero over each single complete cycle.

The computation of all of these can be seen in the spreadsheet at
http://keith.dysart.googlepages.com/generator%2Cline%2Cload%2Creflection

Recall that: cos(a)cos(b) = 0.5(cos(a+b) + cos(a-b))

The power in the resistor is computed by multiplying the voltage
Vrs(t) = 82.46 cos(wt -30.96 degrees)
by the current
Irs(t) = 1.649 cos(wt -30.96 degrees)
yielding
Prs(t) = 68 + 68 cos(2wt -61.92 degrees)

For reflected power at the generator
Vr.g(t) = 42.42 cos(wt +90 degrees)
Ir.g(t) = 0.8485 cos(wt -90 degrees)
Pr.g(t) = Vr.g(t) * Ir.g(t)
= -18 + 18 cos(2wt)

Note that I previously made a transcription error in the sign
of one of the terms.

So X.inst + Y.inst is actually 68 + 32 cos(2wt).

This is a test to see if interference exists. It turns
out that constructive interference exists for the
first 90 degrees and third 90 degrees of the forward
wave cycle. Destructive interference exists for the
second and fourth 90 degrees of the cycle. The magnitude
of the destructive interference exactly equals the
magnitude of the constructive interference as expected
so the net interference is zero as expected.

>
> I think you are mixing average energy flow (the 50 and 18 watts) with instantaneous flow (50 cos(2wt) and 18 cos(2wt)).

I do not think so.

The instantaneous energy flow for the reflected wave is
Pr.g(t) = 18 - 18 cos(2wt) (see correction in previous post)
This means that at t=0, 0 energy is flowing.
When 2wt is 180 degrees, 36 joules per second are flowing.
The average over a full cycle is 18 W.

So I am summing the instantaneous flows for the two contributors of energy.

The correct sum, however, is 68 + 32cos(2wt).

The actual dissipation in the source resistor is
Vrs(t) = 82.46 cos(wt -30.96 degrees)
Irs(t) = 1.649 cos(wt -30.96 degrees)

Prs(t) = Vrs(t) * Irs(t)
= 68 + 68 cos(2wt -61.92 degrees)

Whenever cos(2wt-61.92degrees) is equal to 1, 132 joules per second
are being dissipated and whenever it is equal to -1, 0 joules are
being dissipated. This follows from the periodic nature of the energy
flow.

> I think Z.inst = x.inst + y.inst = 50 cos(2wt) + 18 cos(2wt). The two energy components arrive 90 degrees out of phase (in this example) so we should write z.inst = 50 cos(2wt) + 18 cos(2wt + 90).

The error in your calculations has been diagnosed.
Since interference exists at the instantaneous level,
it is invalid to add the instantaneous powers directly
as you have done.

Hint: if (V1^2 + V2^2) is not equal to (V1 + V2)^2
then it is invalid to add powers directly. Everyone
should have learned that fact in EE201 when the
professor said: "Thou shalt not superpose powers".

An invalid thing to do when interference is present.
Reference EE-201 to find out when and why

[V1(t)^2 + V2(t)^2] is NOT equal to [V1(t) + V2(t)]^2.

The whole premise and assertion that the dissipation
in the source resistor is equal to 50w plus the
reflected power is based on the condition that

(V1^2 + V2^2) is equal to (V1 + V2)^2

Since you did NOT satisfy that condition, it
logically follows that the assertion would not
apply unless that necessary condition is met.

Please get back to us when you meet the above
condition. In attempting to do so, you will
realize why Eugene Hecht said that instantaneous
power is "of limited utility".

Even that might not be adequate, depending on the design of the transmitter. Any power or other wires connected to the transmitter could easily become part of the radiator, so they'd have to be decoupled. A small, battery-powered transmitter with no connected wires would avoid this potential problem.

So the question is "When does (x + y)^2 = x^2 + y^2 ?".

(x + y)^2 = X^2 + 2xy + y^2

X^2 + 2xy + y^2 = x^2 + y^2 only when either x or y = zero.

Since it's a linear system, no matter where the "reflected" wave is coming from (that is, whether it's actually a reflection, or from some completely separate source which may or may not be on the same frequency), I believe until someone shows me differently and proves the multitude of analyses showing it to be so, that the reflection coefficient going from the line back into the linear source really does work, and it works at every instant in time.

The paragraph quoted above, then, begs the question: if not in the resistor, where? The answer should be perfectly clear.

Cheers,
Tom

> . . .

Fair enough. But only the naive will be impressed by an antenna system that has to be electrically large (including the feedline) in order to be efficient, unless it also has some property that's significantly different than the radiating feedline alone. For example, it would be interesting if it's highly directional when fed with a vertical feedline, but not if it just looks like another vertical.

If the feedline is radiating, you can expect the antenna performance to be quite sensitive to the conductive path from the transmitter to the Earth, as well as the feedline length and orientation. Consequently, different people will likely get considerably different results, even with identical antennas and feedlines. So the entire path from the transmitter to the Earth will have to be specified and carefully duplicated in order to get meaningful and repeatable results if the feedline is a critical part of the system.

That's some "Food for Thought", Roger, but unfortunately
phasor math is more complex :-) than that. The "Rest of
the Story" is if x and y are phasors that are 90 degrees
out of phase with each other, is there another solution
besides the one you offered?

Given two phasors, 1v at 0 degrees and 1v at 90 degrees,
what is the sum of the square of the voltages vs the
square of the sum of the voltages. Hint: the phasor sum
of the voltages is 1.414.

What you seem to be missing, Tom, is that if the two signals
are not coherent, interference is not possible. Since we are
discussing interference effects between obviously coherent
forward and reflected waves, your observation seems to be a
moot point.

For instance, if the forward and reflected traveling waves
in Roy's "Food for Thought" page are replaced by two sources
that differ by 30% in frequency, there is no way for that
entry in his chart to reach the 400 watts dissipated in the
source resistor.

BTW, I apologize for my outburst last night. I just get friggin'
tired of the "Have you stopped beating your wife?" questions.

Being from a broadcast background and new to ham radio, I'm trying to find sample ports to connect scopes and spectrum analyzers to radios and dummy loads. I'm not finding any and have been simply using UHF Ts and small loops of wire near finals and radio outputs as sample ports.

Am I missing something or is this normal?

What are other people doing to get a scope sample port on an antenna to make power calculations?

I'm Ting off between the xmitter and tuner to feed the scope to look for flat topping and power calculations as this point should be 50ohms but suspect this is not normal as the xmitter output is fully feeding the scope trhough a x10 probe.

I assume you are talking about SSB telephony.

If you are just wanting to monitor the waveform for flat topping,
absolute calibration is not necessary and you could just use another
short antenna as a pickup.

I would argue that an inline directional wattmeter with PEP peak hold
amplifier is a more reliable way to measure power, and is a more
reliable indicator of occasional voice peaks which you may well not see
on a CRO.

OK, The vector sum is sqrt(1^2 + 1^2) = sqrt(2) = 1.414

I would think of the "square of the sum of the voltages" to be (1 + 1)^2 = 2^2 = 4

We must be very careful to not use scaler math when vectors are called for.

Take a look at the schematics for the LDG or SGC autotuners. They both
have some form of bridge circuit, and the SGC detects the sign of the
relative phase.

One can use, for instance, the phase frequency detector from a PLL (i.e.
a JK flipflop appropriately wired) to compare the relative phase of
forward and reflected powers from a bridge. (and, for your application,
you don't need a calibrated bridge..)

For HF purposes, there's a lot of digital circuits out there that are
fast enough, and for the usual antenna tuner kind of application, you've
got enough signal.

You still don't understand! you are talking bullshit you have no
idea of the design of Art's antenna or of how it works or it's needs
yet you put up your remedies for old style antenna's.

I am sure Denny is a competent and independant operator and will be
aware of all the pitfall's of testing a new antenna and does not need
you to tell him how to go about it.
As Art said in a previous post Denny is free to do as he wishes Art
will have no input in the testing of the antenna, and nor should you

Keep on digging the hole is getting bigger.

Objectively, Derek, for what reasons are you are so willing to believe the claims that art makes for his "highly-efficient," shoe-box MW antenna, and for your confidence in Denny's ability to measure its radiation characteristics scientifically?

No BS, please. Facts count -- emotion does not.

Well, where is the beef? Do you have any actual data to support
these magic claims? Hummm.. Thought not..
I'm using actual experience with antennas to support
my disbelief. If what he says is true, I'd likely already
be using one.. I'm not against a dinky 160m antenna
with full size performance. But until I actually see
one work... Well, you might get it, or you might not..

How can I live in the past? I can only remember the past.
And *nowhere* in the past have I ever seen such a
device actually work as claimed.
So put up the data, or you get to digging...
You kind of remind me of that "Bret" dude who calls himself
John Smith, or whatever... :/
I'd rather be a slopehead than believe in the tooth fairy,
free lunches, and antennas that don't follow the rules
of science.
I have no doubt his antenna may radiate some..
But then again, most dummy loads do also..
Tales of QSO's using light bulb dummy loads used to be
quite common back in the past, which I can still remember
going back to the time of swatting at colorful plastic butterflies
hanging above my head in my baby crib.

For some reason, I'd always got the impression that the antenna
was symmetrical and balanced.. But who ever knows for sure
with Art...
If this is the case, I wonder why he needs the garbage can lid, or
whatever metal he is using under it..
I had the impression in his various posts that he was trying to
avoid ground connections. But whoever knows for sure except
Art, and now maybe Denny... :/

There is NO WAY I'm interested in moving to a one-dimensional world that requires me to special-case a particular type of wave to get the right answer and FORSAKE the multi-dimensional linear circuits world I'm in, that quite accurately describes what happens regardless of the content of forward and reverse. Your one-dimensional world apparently limits you to thinking about interference in a way that mine does not. I may post the results of a 'speriment I'm setting up in a day or two that may spark some interesting discussion. Till then, I'm outta here.

Cheers,
Tom

How coherent do the two signals have to be for interference to
occur?

You say that when the sources are coherent, interference occurs
but when the frequency differs by 30% it does not.

What happens if one of the sources has just a bit of phase noise,
or the frequency wanders just a bit, or is just offset a bit?

How much of a difference does there have to be for interference
to stop? What is the threshold? Phase noise? Wander? Offset?

And is it the mechanism that creates interference that stops working
once the threshold is crossed?
Or does the mechanism still work, but we just no longer call the
result interference? Why do we stop calling it interference once
the threshold is crossed?

What is the mechanism that creates the effect we call interference?

Hi Keith,

I must still not be "getting" something because while I now follow your numbers and trig identity, it looks to me like you used Cecil's premise "PRs = 50w + Pref " to show that '50 W plus Pref' = 68 + 68cos(2wt-61.9degrees) watts, which would be correct for the 12.5 ohm case.

So, rather than disproving Cecil's premise, you successfully demonstrated that it was correct in the instantaneous case.

What am I missing?

Coherency, non-coherency, and interference is covered well
in "Optics" by Hecht and other textbooks. Optical physicists
have been tracking the EM energy flow for centuries. This
information may be new to you but it is old hat in physics.

What I have proved in Part 1 is that average reflected energy
is not always reflected back toward the load. Equally false
is the flip side old wives tale that says: "Reflected energy
is always dissipated in the source."

It's takes only one case to prove an old wives' tale to
be false. That's why I chose the special case of zero
interference. One needs to understand the special case of
zero interference before one tries to understand the general
case involving interference which will be Part 2 and Part 3
of my articles.

If you choose to remain ignorant, "NO WAY I'm interested",
then that's your choice and that's OK. But understanding
interference is the easiest way I know of to track the
energy flow.

If you come up with an easier analysis of average energy flow
and average power, that will be great.

>
> So, rather than disproving Cecil's premise, you successfully demonstrated that it was correct in the instantaneous case.
>
> What am I missing?

The actual dissipation in the source resistor was computed using
circuit theory
to derive the voltage and current through the resistor and then
multiplying them
together to get the power dissipation:
Vrs(t) = 82.46 cos(wt -30.96 degrees)
Irs(t) = 1.649 cos(wt -30.96 degrees)
Prs.circuit(t) = Vrs(t) * Irs(t)
= 68 + 68 cos(2wt -61.92 degrees)

This was then shown not to be equal to the results using Cecil's
hypothesis
because
Prs.before(t) = 50 + 50 cos(2wt)
Pref(t) = 18 - 18 cos(2wt)
which would give, using Cecil's hypothesis
Prs.cecil(t) = 68 + 32 cos(2wt)

So I accept the circuit theory result of
Prs.circuit(t) = 68 + 68 cos(2wt -61.92 degrees)
and conclude that, since the results using Cecil's hypothesis are
different, Cecil's hypothesis must be incorrect.

That is, the power dissipated in the source resistor after the
reflection
returns is not the sum of the power dissipated in the resistor before
the
reflection returns plus the power in the reflected wave.

Now it does turn out that the average power dissipated in the source
resistor is the sum of the average power before the reflection returns
plus the average power in the reflected wave since
Prs.circuit.average = average(68 + 68 cos(2wt -61.92 degrees))

= 68
This does agree with Cecil's analysis using average powers. But energy
flows must balance on a moment by moment basis if energy is to be
conserved so when we do the instantaneous analysis we find that
Cecil's
hypothesis does not hold.

...Keith

PS: To compute Vrs(t) and Irs(t) using circuit theory:
The generator output voltage
Vg(t) = Vf.g(t) + Vr.g(t)
where Vf.g(t) is the line forward voltage at the generator
and Vr.g(t) is the line reflected voltage at the generator.

The generator output current
Ig(t) = If.g(t) + Ir.g(t)
where If.g(t) is the line forward current at the generator
and Ir.g(t) is the line reflected current at the generator.

Where Vs(t) is the source voltage
Vrs(t) = Vs(t) - Vg(t)
Irs(t) = Ig(t)
and the power is
Prs.circuit(t) = Vrs(t) * Irs(t)

And yet, all we are given is "This is my design, it works, accept it!"

This whole thing smacks of alternative science, where everyone is
required to suspend disbelief, maximize credulousity (is that a word?
;^)). Everyone has to accept it as true, and if you don't you are
subject to attacks. Somehow it becomes the job of the establishment to
prove it correct, and if they don't, it is discounted as conspiracy,
professional jealousy, incompetence, or in some of the more amazing
examples, not enough people believing in it..

Copper bracelets, magnetic water and bedsheets, super duper gas mileage
enhancers that Detroit doesn't want you to have, pyramids, crystals,
thought amplifiers, cold fusion, and on and on and on.

http://www.quackwatch.org/01QuackeryRelatedTopics/signs.html

It's all there. Perhaps this is real, perhaps a new day is dawning in
antenna design. I would never dream of pronouncing the antenna a
non-starter with the paucity of information given. But a whole lot of
what is in that guide is here too.

Not the least impressive is that this revolution is starting in
rraa..... ;^)

Another possibility... since this whole 'tenna thing is working outside
of the mainstream, maybe they'll take it on over at "Mythbusters". You'd
have top admit that Kari would be a lot more pleasant to verify these
claims with than most of us here......

Instead of spending hours typing the answer, I will point
you to "Optics", by Hecht, 4th edition, Chapter 12, Basics
of Coherence Theory.

In my example, the one source is an ideal single frequency
source. Thus all signals existing within the system are
completely coherent, by definition. Your questions are
irrelevant to the example provided.

> You say that when the sources are coherent, interference occurs
> but when the frequency differs by 30% it does not.

In between "completely coherent" signals and "completely incoherent"
signals is a very large gray area. Please read the reference.

> What happens if one of the sources has just a bit of phase noise,
> or the frequency wanders just a bit, or is just offset a bit?

Please read the reference. In my example, the source is ideal
so that problem doesn't exist.

> How much of a difference does there have to be for interference
> to stop? What is the threshold? Phase noise? Wander? Offset?

Please read the reference. In my example, the source is ideal
so those problems don't exist.

> And is it the mechanism that creates interference that stops working
> once the threshold is crossed?
> Or does the mechanism still work, but we just no longer call the
> result interference? Why do we stop calling it interference once
> the threshold is crossed?

In "Optics", by Hecht, Chapter 7 is on superposition and
Chapter 9 is on interference.

Quoting "Optics", by Hecht, Chapter 12. "Thus far in our
discussion of phenomena involving the superposition of waves,
we've restricted the treatment to that of either completely
coherent or completely incoherent disturbances. ... There is
a middle ground between these antithetic poles, which is of
considerable contemporary concern - the domain of
partial coherence.

> What is the mechanism that creates the effect we call interference?

"Interference", in this context, is not defined in the IEEE
Dictionary. The closest I can come to a definition is from
"Optics", by Hecht: "... optical [EM] interference corresponds
to the interaction of two or more lightwaves yielding a resultant
irradiance [average power density] that deviates from the sum of
the component irradiances [average power densities]."

Roger, my premise has nothing to do with the instantaneous
case. I have made no assertions about instantaneous values.
My formula applies *only to average power*. Using that
formula on instantaneous values is an invalid thing to do,
a misuse of the tool.

Not disagreeing - just expanding:
Superposition is certainly necessary but superposition
alone is not sufficient. Superposition can occur with
or without interference.

The definition of irradiance is the "average energy per unit area per unit time". Any deviation away from "average energy per unit area per unit time" when discussing what I have said is a straw man diversion, not in the spirit of a good will discussion.

Cecil,

You may or may not already know this, but a lot of detailed optical analysis these days is done with full 3-D electromagnetic simulation, starting from Maxwell equations and boundary conditions. Interference, coherence, energy flow, and all of the other stuff you like to discuss can be *output* from that analysis, but those items are not part of the input. The "centuries old" optics simply does not get the job done. The "centuries old" stuff may work in the (impossible) cases where everything is completely lossless and ideal, but it doesn't give the right answers in the real world.

If we could only get Kari Byron to do the show wearing a thong bikini. In fact, all of the shows could be improved in a similar manner.

I would think that lots of new approaches in science began as "alternative science/pseudo science" ideas. No, I can't name one instance off the top of my head. Those instances are missing along with most of my hair, a good portion of my previous superior cognitive abilities and short term memories.

Some of the younger folks' minds have been prepared for the acceptance of dimensional additions to our present paradym of physical reality. I agree (or hope) that soon, other quantifiable aspects of additional dimensions will pop into our reality. It would be interesting to play with the effects of hyperdimensional physics in regard to our antennas. But, at the moment, at least for we old fogies, we are stuck with playing within the current four dimensions.

"Contemporary" is an interesting word choice. Partial coherence has been recognized for a long time. There is a very widely referenced paper by H. H. Hopkins on partial coherence in optical imaging systems that was published in 1950. He did not invent the concept, but he did popularize the standard formulation still used today. The math is a bit messy, with 4 dimensional integrals and other complications, but numerical solutions are widely done.

I would be quite surprised if the radar and other RF experts don't use the same type of analysis.

Oh, by the way, even a completely monochromatic wave can be partially coherent if the source is extended. Indeed, that is one of the more common configurations.

The definition of irradiance, according to NIST, is power per unit area.
The standard units are W/m2 or lumen/m2.

You can add average, peak, instantaneous, or whatever you like to
further define your quantity of interest. Such additions, however, are
not part of the standard definition of irradiance.

I find myself surprised at your insistance that the instantaneous case must be seperated from the average case in our example of waves on a transmission line. Our ability to measure within the confines of the sine wave is much greater than what is possible at optic frequencies so we are led to expect much more than averages.

It is informative to look at each problem from many angles. Keith's method is one way. Another way is to observe that when we begin considering what is happening with the source resistor, we are really bringing the source resistor into the circuit, i.e., bringing the source resistor outside of the 'black box'. Once we do that, we can see that the source prereflection load is not the same as the post reflection load. From this perspective, the equation "PRs = 50w + Pref" becomes a target to which we adjust the source voltage to acheive. We would accomplish that by using your equation but Keith's method.

It seems to me like Keith is using interference, both constructive and destructive, to calculate what the source load would be on the instantaneous basis. To me it seems like a validation of your premise.

Did I misunderstand your premise, and you were really trying to say that the inclusion of a 50 ohm source resistor would prevent the source from ever 'seeing' anything but a 100 ohm load? I don't think that was your intent.

I think that we would be stupid indeed to believe that "Its all known".
I personally believe that we'll be bending space and zipping off to the
galaxies(will that get us away from reality tv?) at superluminal "speed"
in the future. Who knows, we may even become immortal some day.

The skeptics have been wrong in the past. History is littered with them.

But, and this is very important, to pop that old chestnut in the
campfire as some sort of invalidation of the skeptics is not only a
non-sequitar, but really bad logic.

It does not follow that Art's antenna works because the Catholic church persecuted Galileo, and was proven wrong.

His works have to stand on their own merit, not Galileo's.

I have great difficulty following what he writes. It is possible that I am hopelessly dull, but I don't have that trouble with very many people.

Attempts at getting clarity have usually been met with his belief that if you don't get it right away, you have to "go back to school, or remarks similar.

What I have been able to garner of his theory of operation seems to be that electrons, or particles or something, is jumping off the antenna into the "aether", or something like that (zero point energy? quantum matter pops? dark matter? cosmic Vicks Vap-O-Rub?) I dunno for sure - as I is a dull boy sometimes...

Ideal examples are time-honored ways of discussing concepts
and getting away from the vagaries of the real world. If one
understands the ideal examples, one is in a position to then
proceed to understanding the real world. If one fails to
understand the conceptual principles underlying the ideal
examples, one cannot possibly understand the real world.

Your posting seems to reflect your usual sour grapes attitude.
I will expect you to object to every example that uses lossless
transmission lines from now on including ones by Ramo & Whinnery,
Walter Johnson, Walter Maxwell, J. C. Slater and Robert Chipman.

Exactly how much power can exist in a zero unit of
time?

You previously objected to things that don't match
the real world. Instantaneous irradiance would rely
on an infinitesimally small amount of time, something
that doesn't match reality very well. One would think
you would therefore object to the concept of instantaneous
irradiance since it cannot be measured in reality and
exists only in the math model in the human mind.

I have searched quite a bit for evidence that states that performance
of antennas can be rated by it's size. Formulas do not refere to
radiator size or volume
and aparture is referenced to gain. I understand that sort of thinking
based on Yagi design
but the idea that all small radiators are inefficient is rather
ludicrouse. My work, based on
the sciences of the masters, show that a efficient radiator can be any
size,shape and
configuration as long as it
is in equilibrium . Period
No where can I find reference to "size" in what the masters state

As energy per unit time is power, Cecil`s definition agrees with what my dictionary says:
"Irradiance-The incident radiated power per unit area of a surface; the radiometric counterpart of illumination, usually expressed in watts/cm, squared."

This is different from Poynting which uses instantaneous values.

Best regards, Richard Harrison. KB5WZI

The work by Chu (Journal of Applied Physics, p1163, v19, Dec 1948) and subsequently by Harrington (IEEE Trans Ant & Prop, V18#6, Nov 1965, p896) , Thiele (IEEE Trans on Ant and Prop, v51, #6, June 2003, p1263) and later others, discusses fundamental limits on performance. Watch out, though, for the assumptions in the constraints (e.g. whether the device attached to the feedpoint is reciprocal), and, of course, where the boundary of the system is.

Watch out also for the definition of "Q", which in this context is the ratio of stored to disspated/radiated energy, not the ratio of center frequency/bandwidth.

In short, there is a tradeoff between Q, directivity, and size. And, because high Q implies high stored energy, for physically realizable antennas with loss, efficiency is in the mix too.

Googling "chu harrington limit" often turns up useful stuff.

I cannot argue with your point of view, Mike. We must stick with real science and what has been proven when it comes to performing professionally.

However, being somewhat of a conjurer/writer of fiction, I like to permit myself to venture from the accepted path from time to time. I suspect that many scientific breakthroughs have been seeded and brought to fruition over the centuries in much the same way.

I am not defending the OP's position. That is his job, not mine.

You have misunderstood what I am objecting to - which is:
Please don't say or imply that I have said or implied
anything about instantaneous values. I have NOT done so!
The formulas and concepts being used in the discussion
of instantaneous values are NOT mine! My objection is
to the false statements being made about what I have
posted.

Please go ahead and have your instantaneous discussion with
Keith but please don't say or imply that anything associated
with that discussion is about anything I have posted. Saying
or implying such a thing is simply false.

> It is informative to look at each problem from many angles.

I agree - just stop saying that it is based on my assertions.
You or Keith may be right or wrong but either way, it is not
associated with anything I have posted. Please leave my name
out of any discussion concerning instantaneous values.

> Did I misunderstand your premise, and you were really trying to say that
> the inclusion of a 50 ohm source resistor would prevent the source from
> ever 'seeing' anything but a 100 ohm load? I don't think that was your
> intent.

Please add a dimension to your thinking. No matter what the
value of the load resistor, the source delivers 100 watts.
There are an infinite number of loads that the source could
"see" besides 100+j0 ohms that will make that condition true.

When the load is 0 ohms, the source "sees" 50+j50 ohms.
When the load is 12.5 ohms, the source "sees" 73.5+j44.1 ohms.
When the load is 25 ohms, the source "sees" 90+j30 ohms.
Only when the load is 50 ohms, does the source "see" 100+j0 ohms.

One good example, I think, is the theory of continental drift -
originally viewed by the mainstream as being pseudoscience (or at
least unproven), now adopted as "plate tectonics" and acknowledged as
a critically important process in the evolution of our planet.

In order for any "alternative science" theory to achieve mainstream
acceptance, I believe that it has to demonstrate the sort of
characteristics that other (mainstream) scientific theories do.
Specifically:

- It has to be falsifiable. The proponents of it have to be able to
say "OK, if it's wrong, here's how we could tell".

- It has to make testable predictions.

- It has to do a better job with those predictions, than the theories
against which it is competing. It must either (accurately) predict
things that other theories cannot predict, or (in some cases) it
must predict the same things as other theories predict, but do so
in a more "elegant" way.

Testability and falsifiability are the key issues, I believe.

Art has been talking about nontraditional antenna design ideas for
years. To the best of my knowledge, this is the first time he's ever
actually provided a sample for an independent party to test.

I think it's only fair for the parties doing the testing, to be
allowed to perform whatever sorts of tests they feel are appropriate,
and report accurately on the test conditions and the results.

If Art or his proponents feel that some of these tests are invalid
(due perhaps to new, nontraditional theories about how the antennas
are supposed to function), then it's up to them to express these new
theories in some testable, falsifiable form, so that the theories can
be fairly evaluated by others.

You can sure say that again...in fact, Maxwell doesn't really do it
either when you get to quantum mechanical effects. But that's a story
for another day.

Certainly, those who design and build FTIR spectrometers know
perfectly well that interference does not depend on a narrow-band
coherent source. Blackbody radiation works just fine, thank you. But
it doesn't take much beyond belief in linear systems to understand
that. I recall explaining to a company VP how it worked in terms of a
linear system, and it was very gratifying to see the virtual light
bulb lighting up in his head...he really got it.

Cheers,
Tom

How narrow-band? How coherent? In the irradiance (power
density) equation, Ptot = P1 + P2 + 2*sqrt(P1*P2)cos(A),
if the angle 'A' is varying rapidly, what value do you
use for cos(A)?

A constant average sustained level of destructive
interference cannot be maintained between two waves
unless they are coherent. If they are not coherent
the interference will average out to zero.

Art wrote:
"No where can I find reference to "size" in what the masters state"

More diligence!

Terman never failed to have an answer for me. On page 864 of his 1955 0pus he writes:
"The simplest wire radiator or antenna is the elementary doublet shown in Fig. 23-1a. This consists of a conductor of length small-delta l that is short compared with the wavelength lambda, and which is assumed to have such large capacitance areas associated with each end that current flowing throughout the length of the doublet everywhere has the same value I. The strength E of the field radiated from such an elementary antenna in volts per unit length by a current I cos (omega t + 90 degrees) is given by the formula
E = 60 pi/d l/lambda Icos theta cos omega (t-d/c)
Eqn. (23-1)
Here d is the distance from the doublet to a distant receiving point P, and theta is the direction of P with respect a plane perpendicular to the axis of the doublet while c is the velocity of light. The strength of the radiated field is distributed in space in accordance with the doughnut pattern with a figure-of-eight cross section shown in Fig. 23-1b."

The above is only the beginning of Terman`s chapter on antennas. Fig. 23-2 shows how contributions from multiple doublets in a larger antenna combine to produce the pattern of the larger antenna. Point to be noted is that length over lambda is a multiplier in Eqn.(23-1). Obviously size (length) does make a difference.

Best regards, Richard Harrison, KB5WZI

Hello everyone

Like Mike, I also have the MFJ-1800. And boy was I surprised when none of my shack full of type N to SMA adapters didn't work. I can't believe they reversed the polarity of the center pins for WIFI SMA connectors. Urrrrgh !!!

The router discussion is interesting I need to keep it simple. Of my various goals one of them is to passively receive signals. At least at my level of knowledge it will be best if the computer links directly to the adapter.

Haven't had the chance to look around but I do like the Ethernet cable up the tower suggestion. Is there a particularly good adapter for doing this?

Hi Bob,
I have done something similar to what you want to do. I picked up MFJs yagi antenna MFJ-1800
http://www.mfjenterprises.com/man/pdf/MFJ-1800.pdf
and a $13.00 wireless USB adapter. I adapted an N connector to the wireless USB adapter.

(a little troublesome, large connector, small adapter) I then connected the N connector/adapter assy
to the yagi. I mounted the whole thing in a 4" pvc pipe. I purchased two 15 ft USB male to female cords.
I found I had intermitent performance, The problem was 30 ft of USB cords, I cut back to one 15ft cord
and the ass'y works wonderfully. I can see over 20 wifi signals from where I'm at, only 3 to 4 are strong
signals (over 50%, whatever that means). While trying to solve the intermitent performance I did find
there are cords available with amplifiers built inline to extend the usable USB cable length. I did not try
these I just moved my yagi. The others are way ahead of my knowledge regarding the wireless router and
it's operation on top of your tower.
Mike

The FCC requires that Part 15 WiFi devices, having detachable antennas, *must* use connectors which are not the common, generic, off-the-shelf standard types.

This was done in order to (try to) (help) enforce the rule that Part 15 radios, and their antennas, must be certificated as a complete system (radio + antenna), by the manufacturer or by an organization which does the installation.

Manufacturers of such devices can perform the testing certification with several different types of antennas, and using such antennas with that particular device is legal (since they've been certificated as a system).

Plugging an arbitrarily-chosen antenna into a WiFi radio (access point or client) will void the Part 15 certification of the device, and it becomes technically illegal to operate it. That's why a whole bunch of nonstandard (reverse-polarity, reverse-thread, or otherwise altered and perverted) connectors are used... the manufacturers are *trying* to deter people from "one from column A, one from column B" interplugging, because that's what the FCC has instructed them to do.

The rule gets about as much respect as laws against jaywalking, littering, or cussing in South Pasadena during the first week of March, but it's on the books ne'ertheless.

Global warming - or cooling, due to solar flux and independent of internal mechanisms (like us) has been the mainstream knowledge for a long, long time.

Interesting that you chose this one, Cecil.

Mention Al Gore's name, and you can bet that the more neoconservative among us will start the ridicule bandwagon going. They say it is a political thing. It is for them.

Heat retention by the group of gases collectively know as "greenhouse gases" is a fact. Proven time and again in experiments that a high school kid can do.

There is a direct correlation between human activities that release CO2 into the atmosphere, and the percentage of CO2 in the atmosphere. This increase should have an effect on the heat retained by the atmosphere.

Doesn't matter what the CO2 source was. Global warming is just as much a fact as evolution, and opposed by many of the same folks as that one.

Now it is time for those who would debunk it to come up with solid scientific reasons why the effect is not happening, not political ones.

Here are some possibilities:

Humans really aren't putting CO2 in the atmosphere.

That CO2 is different.

The earth wants to maintain a constant temperature, so it somehow ignores that CO2.

Temperature measurements are actually wrong.

That kind of stuff. Give how's and whys. Not political verbiage.

My understanding of your claim was that for the special case of a 45 degree line supplied from a matched source, the energy in the reflected wave is dissipated in the source resistor.

This sentence fragment from your document suggests this:
"reflected energy from the load is flowing through the source resistor, RS, and is being dissipated there".

As "proof" of this, you computed average powers and showed that the dissipation in the source resistor increased by the same amount as the computed average power in the reflected wave.

But when an attempt it made to validate your claim using instantaneous energy flows, the claim is proved false because the dissipation in the source resistor does not occur at the correct time to be absorbing the energy from the reflected wave.

To prove your claim, I can see two paths:
- find some element in the circuit that stores the energy from the reflected wave and releases it into the source resistor at the correct time
- allow the violation of the principle of conservation of energy

On the other hand, if you want to modify your claim to simply be that the numerical value of the dissipation in the source resistor has the same value as the pre-reflection dissipation plus the numerical value of the energy in the reflected wave, then the discrepancy is resolved. But then you can not claim that the energy in the reflected wave is dissipated in the source resistor.

...Keith

Required by Part 15..Has to be a connector with is "not commonly
available". Reverse Polarity SMA and TNC connectors are pretty standard
for this application, to the point where you can get adapters and jumper
cables pretty easily.

So superposition is the underlying mechanism that can be used to
explain all.
Interference is a phenomon that is observed for certain particular
conditions of superposition.

Works for me.

>
> Best regards, Richard Harrison, KB5WZI

I disagree. Laws written are all based on the assumption of
equilibrium and that includes
Maxwell's laws. These laws hav e zero refernce to size as such though
many would seek
for the word volume. Pertinent factors are wave length of frequency in
use and root LC.
For equilibrium there is zero reference to size or volume. I ofcourse
fall back to the term equilibrium
which is a basic for Gauss's law of statics to which a variable time
can be added. Thus it can be seen that

a law can be stated that a radiator can be any size, shape or
configuration as long as it is in equilibrium.
The problem here is that amateur radio is wellded to the yagi design
which is not one of equilibrium
and the fact that amateurs and many of the higher educated have pushed
the term of equilibrium
outside the box. This shows up when the uneducated refer to small
antennas as being inefficient
based purely on the connection to a specific design without regard to
whether equilibrium exists
so that all the laws of the masters can be applied. Again, it is
implicite that all laws apply when
there is equilibrium, if there is not then the laws do not apply as
is.
With respect to the term
"length", this is not synonimous to "size" because it has only one
degree of freedom.
There is no reason why a radiator can be rolled up into any shape as
long as the laws of Maxwell
are adhered to and such a sample has been assigned for testing and I
have to be satisfied with the results
as they arrive.I will be soon using one on the radio for QSO's and I
apologise if its use offends anybody
Seems like the group is in quite a tizzy that a person would have a
small radiator that defies
that which has taken them years to memorize. I gave all pertinent
details how to make them
I also gave the mathematics and a sample where established computor
programs confirm the above
and now to upset all again I have given a sample for testing to a
independent reviewer.
There is no need for anybody to worry, Yagi designs still exist for
those who abore change,worry
about transmission line radiation or even radiators melting. When you
all understand the relevence of
equilibrium you can then procede to review the math, until then you
are all in left field.
Best regards
Art
There is nothing in Maxwells laws that prohibit a "wavelength" from
being condensed into the
size of a pinhead or smaller and still be "efficient" with respect to
stated paramitors.

Michael Coslo wrote:
> Give how's and whys. Not political verbiage.

OK, how about this? Global warming has always run in
cycles of 100K+/- years. Man obviously had no effect
on the previous cycles. The temperature 130,000 ago
averaged 4 degrees higher than any temperature during the
present cycle. The maximum temperature during the present
cycle occurred 8000 years ago when man obviously had no
effect. We are now 8000 years into the next ice age. Any
global warming effect provided by man's greenhouse gases
will tend to delay the plunging temperatures associated
with the presently approaching ice age and save tens of
millions of people from starving to death due to the
farmlands being overrun by glaciers.

http://en.wikipedia.org/wiki/Image:Ice_Age_Temperature.png

Mars undergoes global warming at the same time as the
earth does. Are the Martians emitting greenhouse gases?

Hello,

I have a quite common setup: a 100 watt rig with an antenna tuner feeding into ladder line that runs to a 200 foot dipole up as high as I could get it-- maybe 40 feet.

I've had fun with it, but I'm thinking about stepping up to a linear amplifier. I'm thinking about perhaps 800-ish watts. I can't go to a tower or yagi, as I need to be at least a little secretive.

The wire is 14 guage (stranded) in both the ladder line and in the dipole. Can someone tell me if that will hold up to the increased power? Any tips or other information would be great.

Thanks,
Jim

I have told you time and again that your understanding is
wrong. My claim is that for the special case of a 45 degree
phase difference between the forward wave and reflected wave,
the *average* power in the reflected wave is dissipated in the
source resistor. Irradiance is an *average* power density as
defined by Hecht, in "Optics". I have told you previously (many
times) that when I use the word "power", I am talking about
average power. I agree with Hecht that instantaneous power
is "of limited utility" and is therefore mostly irrelevant.

For the record - for the umteenth time: When I say "power", I
am talking about "*average* power". If I ever talk about
instantaneous power, I will say "instantaneous power". If
you still don't understand, you need professional help.

> This sentence fragment from your document suggests this:
> "reflected energy from the load is flowing through the source
> resistor, RS, and is being dissipated there".

I left no doubt as to what I meant in my document. Here is
a quote from the second paragraph in my document:
"Please note that any power referred to in this paper
is an *average power*. Nothing is being asserted or implied about
instantaneous powers. In fact, instantaneous powers are completely
irrelevant to the following discussion."

I simply don't know how to say it any plainer than that.

I really resent your lack of ethics in this matter.
If you are forced to create a Big Lie about what I have
said in order to try to win, is it really worth it?

>long, long time.

Correct.

I believe that Cecil (like a very great many other people) is falling victim to a classic logical error, commonly referred to as "the fallacy of the excluded middle" or "false dilemma".

In this instance, Cecil's statement carries with it an implied assumption: that global warming (assuming that it exists) is due *either* entirely to the effects of the sun, *or* entirely to the effects of mankind. Cecil's statement implicitly denies the possibility that *both* of these factors (as well as others) may in fact be contributing to whatever warming, cooling, or other climate change is occurring.

Taking such an exclusionist position can certainly be convenient. If you can define the terms of the debate in this way, then all you have to do is prove *some* truth to your own side of the argument (e.g. demonstrate that solar changes do have effects on Earth's temperature), and by exclusion you have "proved" the falsity of all of your opponent's arguments and evidence. I've seen this tactic used by those arguing both sides of the global-warming debate.

I don't believe that the real world is as simple as this. Measurable effects can have many contributing causes. My own conclusion is that global climate change has both external (e.g. solar and earth-orbital) and internal (greenhouse-gas) origins, and that at least some of the latter are heavily influenced by human activities.

As to the relative contributions of these internal and external forcing functions to the final climate on this planet... we have to depend on theory, modelling, and experience to figure that out.

To me, the really scary possibility is that the combined effect of internal and external stimuli will push the system out of one mostly-stable state, and into another, through a difficult-to-reverse

toggle point. Warming and drying up the Amazon far enough to make it
flip over from rainforest to savanna might be one such toggle.
Warming up the deep ocean enough to start melting a large quantity of
methane hydrates would be another.

Gee, I wonder if the experts may have moved beyond the elementary optics textbook descriptions?

Are you suggesting that FTIR cannot work unless one has your nice 1-D configurations with perfectly monochromatic waves? Does everything need to be collinear and coherent?

Have you stopped beating your wife? Please cease and
desist with your diversions in the form of innuendo.

It is not my fault that a transmission line is essentially
one-dimensional but I am willing to take technical advantage
of that fact of physics. It is not my fault that CW transmitters
emit essentially monochromatic waves but I am willing to take
technical advantage of that fact of physics.

David,
You admit to not understanding the term "equilibrium" so what do you
care what I say and in what content.
If you consider a half wave dipole as being in equilibrium you have to
consider the electrical circuit
consisting of a capacitance from the antenna to ground or the route
thru the center of of the radiator, both of thes circuits
can be considered as being in equilibrium. However, on this newsgroup
a fractional wavelength radiator is considered as an open circuit for
some reason and thus under those circumstances the half wave dipole is
not in equilibrium.
Now your views on radiation is all over the place so it is very hard
for me to determine the context of what you say.

YOu are good for the maximum legal power plus some. A dipole made out of
almost any size wire and especially # 20 and larger will handle a KW without
any problems.

> If you consider a half wave dipole as being in equilibrium you have to

no, it wasn't me that said that, you said that a half wave dipole was an
example of your equilibrium gaussian antenna. don't put words in my mouth,
i don't think any antenna is in 'equilibrium' if it is working right, there
is always a flow of power either in or out... equilibrium means not going
anywhere, i want my antennas to radiate and receive, not just sit there and
look pretty!

Long before we rode our dinosaurs to club meetings the bright lights had completely agreed that the strength of radio signals at far off places was a function of the integral of i·dl where dl is the bigness of the aerial. Maybe it's in Sears and Zemansky. I dunno . . nor do I really care.

Nothing wrong with that with respect to yagis it just doesn't refer to
all antennas

Cecil must have flunked calculus. Also, differential calculus is
the life-blood of classical electromagnetic theory. The ancients used
it liberally. Cecil probably doesn't believe in speed, because speed is
also an instantaneous quantity. Maybe he can use his argument on the
next ham-fisted Texas trooper who stops him for speeding on his motorcycle.

Hi,

Thanks for all the previous help.
Realize they are all pretty basic questions, and appreciate the help very much.

Am in my 70's now, and keeping up with a lot of this stuff is getting to be a bit more difficult. Greatr hobby, though.

For a receive-only run to a scanner. I'm assuming that I am interested in up to one GHz, absolute max.

Expect to go with F connectors on the coax as they are so readily available already made up, and relatively inexpensive.

Anyone feel strtongly that it is worth going the BNC or the N route, or can I probably be happy with the F's ?
About a 50 foot run. In practice, would I even see any difference ?

I plan on RG6U, Quad Shield, probably

Saw it at Lowe's of all places. Brand was Philips.
Looked pretty good (I think); gold plated F's, and quad shielding.

Thoughts on ?

Just as a sidelight, I also have a sw set, and have all N and BNC on my PAR antenna to the sw set run, though.
LMR 400 coax used. About 125 ft run here.

Thanks,
Bob

> Googling "chu harrington limit" often turns up useful stuff.

Googled Chu harrington and find that his work is basically empirical
around known arrangements.
When he brought the question of Q into the picture he made the
statement that small antennas
are usually of a low impedance which is correct empirically with
respect to existing designs but it is not exclusive
when dealing with all radiators that can be made that comply with
Maxwells laws. As I have said before it is implicite in Maxwells laws
that a efficient radiator can be any size shape or configuration as

long as it complies with Maxwells law.
In my case my small antenna can have any impedance value for equilibrium and it is quite easy to have a resistive impedance in the hundreds of ohms as well as minuit impedances. I conform to 50 ohms purely because of component availability. As another aside my small antennas
have a much wider bandwidth than any other available! As far as gain or energy transmitted that all depends on what frequencies get thru the bandpass filter and in no way directs out of pass energy to be be redirected to band pass status and augment energy transmitted. Stored energy has no relationship to Q in my mind since it goes around or circulates as with a tank circuit energy that lies within the pass bandof the tank circuit filter.
To summate, my antenna design is considered small yet complies with Maxwells laws and yet does not have a narrow bandwidth or low impedance thus Chu's comments cannot be inclusive of all radiators.
Best regards
Art

F connectors are just fine for that application. You wouldn't see any
difference -- except to your pocketbook -- if you went BNC or N instead.

For receive only I doubt you would see any differance if you just stuck the
center wire in the connector of the receiver and touched the shield to the
connector.

Note. that applies to a particular straight antenna and not to all
radiators as a whole.
Maxwell does not state that a radiator must be straight or any
particular shape for his law
to be applicable.

> said in order to try to win, is it really worth it?

OK. I think I've got it now.

You are *not* claiming that the *energy* from the reflected wave
is dissipated in the source resistor, because for the *energy*
in the reflected wave to be dissipated in the source resistor,
the *energy* would have to dissipate at the same time that the
reflected wave delivered the *energy*, and the analysis of

instantaneous *energy* flows shows that this is not the case.

Rather, you are saying that the average reflected power is numerically equal to the increase in the average dissipation in the source resistor.

I can accept that as correct.

You might consider rewriting the sentence "reflected energy from the load is flowing through the source resistor, RS, and is being dissipated there" since it refers to the energy in the reflected wave and may mislead others in the same way it mislead me.

...Keith

I take it your version is gifted and suffers not from a low Q... :/

>As I have said before it is implicite in Maxwells laws
> that a efficient radiator can be any size shape or configuration as
> long as it complies with Maxwells law.

Sure it can. Common knowledge. It's also common knowledge
that the trick with building a small efficient antenna is not really
the size of the radiator itself, it's actually getting power to that
small radiator.

> In my case my small antenna can have any impedance value for

As far as the rest, my cat has mittens.. :/
BTW, you need to define "equilibrium".
After several months you still are lagging at this task.

I don't think anyone here really knows how you define that word
as it pertains to your antenna design.
Once I saw where you said it meant the antenna was resonant,
"eham?" but that seems to change with the direction of the wind
and the amount of snowfall on the ground.

> cycle occurred 8000 years ago when man obviously had no effect.

Cyclic variation is not the issue. Many things can cause average global temperature to vary. Insolation, the amount of greenhouse gases emitted by other sources, volcanism, possible methane clathrate releases are all modifiers.

During earlier days in our solar system, the sun was a good deal dimmer, like 30 percent, 4 billion years ago. And yet, during much of the time, average global temperatures were higher than today. While creation science argues otherwise:

http://www.creationscience.com/onlinebook/AstroPhysicalSciences10.html

http://www.answersingenesis.org/tj/v15/i2/faintsun.asp

it is quite likely that CO2 from volcanism could take care of that issue.

> We are
> now 8000 years into the next ice age.

And a fascinating ice age it is! 8^) Looking at the timelines of recent ice ages, it is beyond my ability to tell just where we are. If we are in a glaciation period, the interglacial was the shortest one known. By your statement, the interglacial was around 2000 years. But your data and mine are radically different.

> Any global warming effect provided
> by man's greenhouse gases will tend to delay the plunging temperatures

What I see here is the old either/or problem. You can't have it both ways. Because there are natural fluctuations in global average

temperature does not mean that adding our own contribution is negligent.
IOW, it isn't a choice between the two.

Wherever we are in the cycle of global average temperature, and for
whatever reasons we are there, what we are doing is either having an
effect because of physics, or it isn't because of mitigating physics that
we don't understand yet.

What is your real p;roblem? You have not seen my antenna and obviously
dont understand the mathematics
and you are not an engineer, Yet you have made so many comments and
opinions that berate the design and seem un willing to wait until the
independent review comes in. On top of that you want help with the
word equilibrium!.
Give me a break.You should have pursued an education instead of
bragging how often you quit going to school
then you would not appear so ignorant about antennas. Treat it as a
hobby and forget about the being an expert side of things, for you it
is to late. And yes the antenna is resonant but rezonance does not
always equate to equilibrium.
With respect to feeding a small antenna it is not that difficult
especially if you choose a resonance of 50 ohm
resistive. With respect to your world beating antenna that is so easy
when you get rid of those loading antics
that you use. I know you can work all you can hear but what about all
that your inefficient antenna is n0lt hearing?

Hi Dave,

At the risk of becoming a stockade-lawyer, I've perused the band plans (I presume that the 13cM band has not been confiscated in the past few years), and I think I am reasonably adept at the law in this regard. As WiFi shares our allocation; it is noteworthy that we as amateurs are the ONLY service that does NOT require FCC type acceptance to operate. To my mind, the only issue is one of knowingly interfering with a service (that doesn't seem to be an issue, however).

OK Cecil. I understand that none of your discussion applies to instantaneous values, only average values.

I am examining Keith's spread sheet carefully. I found that Open Calc will open the spreadsheet so I can read Keith's cell directions. (Thanks for making the spread sheet available Keith.) I want to make sure that I fully understand what is happening here, to the best of my ability and time available.

Art wrote:
"No where can I find reference to "size" in what the masters state."

It`s there if you look. Kraus is a certified master. In the newest edition, the 3rd, of "Antennas" is found on page 12:
"The basic equation of radiation may be expressed simply as
IL=QV, where
I=time changing current
L=length of current element
Q=charge,C
V=time change of velocity or acceleration
Thus, time changing current radiates and accelerated charge radiates. For steady-state harmonic radiation, we usually focus on current. For transients or pulses, we focus on charge."

The above is the beginning of the chapter on "Antenna Basics". Everyone interested in antennas needs ready access to this important book.

Best regards, Richard Harrison, KB5WZI

Long before we rode our dinosaurs to club meetings the bright lights had completely agreed that the strength of radio signals at far off places was a function of the integral of i•dl where dl is the bigness of the aerial. Maybe it's in Sears and Zemansky. I dunno . . nor do I really care.

w3rv

Antennas for All Applications, 3rd Edition, Kraus & Marhefka, McGraw-Hill, page 12.

<Begin quote>

Regardless of antenna type, all involve the same basic principle that radiation is produced by accelerated (or decelerated) charge. The basic equation of radiation may be expressed simply as

IL = Qv (A m / s)

where

I = time-changing current, A/s
L = length of current element, m
Q = charge, C
v = time change of velocity which equals the acceleration of the charge, m/s

Thus, time-changing current radiates and accelerated charge radiates. For steady-state harmonic variation, we usually focus on current. For transients or pulses, we focus on charge. The radiation is perpendicular to the acceleration, and the radiated power is proportional to the square of IL or Qv.

<end quote>

Cheers,
John

Tell you what... Instead of tweaking you further, I'll just sit back
and
watch the show. Take all the time you want.
I have enough confidence in known "living in the past" theory to see
that what you are trying to achieve, "full size performance and
efficiency
from a very small radiator" is not going to pan out how you expect it
to.

Good luck in the contest.
But when you are ready to divulge the reports of the comparision and
tests, don't be overly offended when people ask pertinent questions
about possible feedline radiation and other sorts of RF augmentation,
intentional, or not. Evasion of these questions will invoke my
tweaking
reflex, which could get ugly to passersby. :/

Hi Richard,

It takes Laport only 3 pages to name three references for the math (Stratton, Skilling, and Kraus); provide the equation; and directly state at the bottom of page 3:
"directly proportional to the current and to the
continuing on top of page 4:
"length of the doublet..."

No requirement for resonance, no mention of Q, the only resistance is that of free space, nothing about equilibrium, just a straight answer. The math has been confirmed by experiment, and it is duplicated in models that are fully consistent with all scientific enquiry for the past three centuries which exhibit every quality of the math and the quotation above. The text has been made FREELY available here. No need to purchase.

There are no pages with pictures to color, so reading that far can be tough to master for one finding it difficult to search this out:
>>I have searched quite a bit for evidence that states that performance
>>of antennas can be rated by it's size.
"Quite a bit" sets the standard for the whimpering of whipped dog denial. If just a teensy-weensy bit more effort were made, it is obvious the complete investment in antennas the size of a cracker-jacks box would collapse like the home-loan industry.

But you arer forgettfull Richard, my antenna is a full wavelength
which meets
Maxwells requirements, it is just that the volume is small despite the
wavelength.
It is also not in conflict with "antenna basics" alluded to above. I
don't
understandwhat the beef is. Why are so many hams alarmed at the idea?

Art wrote:
"---my antenna is a full wavelength which meets Maxwell`s requirements, it is just that the volume is small despite the wavelength."

In 1949, I worked at the KPRC-KXYZ broadcast plant. Another operator there, J.L. Davis, W5LIT had a new 1949 Ford in which he installed a surplus ART-13 and a PE-103 dynamotor. For an antenna he wound wire turn by turn on a bamboo pole until it was resonant on a slice of the 75-meter band.

When J.L. modulated, Q in the coil produced a tip corona on the first good peak and modulation became loud without a receiver.

The 20th edition of the ARRL Antenna Book on page 16-13 says this about continuously loaded antennas: "The general approach has been to use a coil made from heavy wire (#14 or larger), with length-to-diameter ratios as high as 21. British experimeters have reported good results with 8-foot overall length on the 1.8- and 3.5 MHz bands. The idea of making the entire antenna out of one section of coil has been tried with some success."

Art`s antenna containing a "full wavelength" of wire would likely feature a greater loss than J.L.`s 1/4-wave resonant coil from simply a greater length of wire while both have peactances balanced to zero. Art`s lower Q would probably kill the corona, increase the bandwidth, while losing the gain that a fullwave straight conductor enjoys.

Cecil can probably report on results of continuously loaded mobile antennas versus a bug catcher loaded whip in the California shoot-outs.

Best regards, Richard Harrison, KB5WZI

> W4SZ

So--I have a classic Michelson interferometer, and I see the classic ring pattern on the screen at the "output" port. I also have a sensitive microchannel plate detector system that I propose to put in place of the screen, so that I can reduce the light amplitude to where it makes sense to be observing it with the very sensitive detector. In fact, I propose to reduce the light level to the point that the short wavelength light I'm using is only putting a few photons per second into the interferometer. I'll count a significant fraction of those photons and identify where they landed on the microchannel plate. Do you suppose, Gene, that I'll still see the same interference pattern that I saw with the much higher intensity light? Is there any limit to how low a light level I can use and still see the pattern?

If I do still see the pattern, there must be yet another "dimension" I need to add to my understanding of the situation -- not rooted in classical Maxwell e&m.

And of course a dimension that is removed if you think only of average quantities is time; one who thinks only in terms of averages removes the possibility of the deeper understanding that resolution as a function of time allows.

Cheers,
Tom

I clearly stated that my claim is based on a special case zero interference condition - it's even in the title of the article. The instantaneous energy that you (not I) introduced, does not meet the zero interference precondition. Therefore, anything that does not meet the zero interference precondition that I enumerated is an irrelevant diversion. You introduced that irrelevant straw man and tried to make hay out it. :-)

> mislead me.

Since "average reflected power" is dependent upon the "reflected energy", I don't see any problem. Would "average reflected energy" work for you? It should be obvious that, associated with interference during each cycle, destructive interference energy is stored during part of the cycle and delivered back as constructive interference energy during another part of the cycle. The intra-cycle interference averages out to zero.

Many have objected to the term "reflected power" saying it is not power that is reflected but instead is "reflected energy". So I stopped talking about "reflected power" and started talking about "reflected energy". Now you object to the use of the term "reflected energy". Would you and the rest of the guru attack gang please get together on what term you would like for me to use?

most, but not all, of the channels used for wifi fall in the amateur
allocation. so if you really want to be technical be sure you set the
access point on the good channels, as well as adding your call for
identification, filtering content, etc.

Given the superposition of two voltages, when the two
voltages have the same sign, constructive interference
is present. When the two voltages have opposite signs,
destructive interference is present. The destructive
interference during each cycle exactly equals (and
supplies) the constructive interference during the
same cycle so the average interference is zero.

Hi Tom,

The Quantum Efficiency of the eye is between 40% and 50%. The time to convert one photon in a visual receptor is roughly 14 femtoseconds.

I have seen no component that can match the bandwidth, dynamic range, AND sensitivity of the eye.

Side note:

Back in the day, when I did a lot of color processing and printing, I would spend log hours in the darkroom in total darkness.

The only light shedding items were the old Gra-Lab timers, and luminescent tape on the dangerous corners. After several hours, the light output from them was just about nil.

My eyes were totally adapted, full visual purple. At this time, the luminescent tape and dials seemed to scintillate discretely, not the typical overall glow.

I always wondered if I was possibly seeing individual photon effects.

At the risk of over-extending the discussion: one in two events, with
the photoreceptors doing what we would call pulse-stretching as the
mind is wholly incapable of discerning a visual event of less than,
roughly, 10mS duration.

Now you have me quite confused. One moment you agree that
your claim is mere numerical eqivalency and the next you
seem to again be claiming that the energy in the reflected
wave is dissipated in the source resistor.

Can you clarify which is really your claim?

> Many have objected to the term "reflected power" saying

I have never been particularly fussy about the terminology. "Energy flow", "power flow": The latter is often used when, strictly, the former is meant, but there is seldom confusion, except for those excessive pedantics who choose to be confused.

My issue was that you seemed, in that sentence, to be saying that the reflected energy was dissipated in the source resistor. But earlier you had stated that was not your claim. See my request for clarification above.

>Urrrrgh
>!!!

The FCC requires that Part 15 WiFi devices, having detachable
antennas, *must* use connectors which are not the common, generic,
off-the-shelf standard types.

This was done in order to (try to) (help) enforce the rule that Part
15 radios, and their antennas, must be certificated as a complete
system (radio + antenna), by the manufacturer or by an organization
which does the installation.

Manufacturers of such devices can perform the testing certification
with several different types of antennas, and using such antennas with
that particular device is legal (since they've been certificated as a
system).

Plugging an arbitrarily-chosen antenna into a WiFi radio (access point
or client) will void the Part 15 certification of the device, and it
becomes technically illegal to operate it. That's why a whole bunch
of nonstandard (reverse-polarity, reverse-thread, or otherwise altered
and perverted) connectors are used... the manufacturers are *trying*
to deter people from "one from column A, one from column B"
interplugging, because that's what the FCC has instructed them to do.

The rule gets about as much respect as laws against jaywalking,
littering, or cussing in South Pasadena during the first week of
March, but it's on the books ne'ertheless.

I have never used the words "mere numerical equivalency"
so I have never claimed any such thing. The energy in
the reflected wave is dissipated in the source resistor
but you are confused about the timing of that dissipation.
It doesn't happen when you are saying it happens. Some
magnitude of energy is stored and dissipated later in
the same cycle.

Your analysis so far has completely ignored
one additional source of instantaneous energy, namely
the reactive component in the network, i.e. the reactance
of the transmission line. When you account for the temporary
storing of the intra-cycle destructive interference energy
in the transmission line followed by its later release as
constructive interference, you will find that all of the
energy in the reflected wave is dissipated in the source
resistor.

During part of a cycle, energy is lost from the source
resistor into the transmission line. During the following
part of the same cycle, that same energy is recovered
from the transmission line back to the source resistor.

instantaneous power dissipated in the source resistor =
1. instantaneous forward power plus
2. instantaneous reflected power plus
3. instantaneous interference (can be plus or minus)

Your calculations so far have completely ignored that
third term which is a source (or sink) of energy depending
upon what part of the cycle exists.

If Maxwell's equations could be used to answer the
questions that we are asking, why haven't they been
answered a long time ago?

How can Maxwell's equations be used to track the path
and fate of the energy in a reflected wave?

Tom, I am ready to eat crow and apologize to you on this one. My false statement above was a rash assumption based on my aversion to instantaneous values.

Last night, while puppy siting my girlfriend's dog in a Walmart parking lot, I realized that the power density (irradiance) equation as presented by Hecht and others does work at the instantaneous level. Mea Culpa.

The difference between coherent and incoherent signals is not in the rules but in the timing. Keith and I were making essentially the same mistake. Thanks for making me think this one through.

Keith Dysart wrote:
> My issue was that you seemed, in that sentence, to be saying
> that the reflected energy was dissipated in the source
> resistor. But earlier you had stated that was not your claim.

My earlier claim was that the average power in a reflected
wave is dissipated in the source resistor when the forward
wave is 90 degrees out of phase with the reflected wave at
the source resistor. In that earlier claim, I didn't care
to discuss instantaneous power and thus excluded instantaneous
power from that claim.

For instantaneous values, it will be helpful to change the
example while leaving the conditions at the source resistor
unchanged. Here's the earlier example:

```
Rs Vg Vl
+----/\/\/-----+----------------------+
| 50 ohm |
| 1/8 WL |
Vs 45 degrees 12.5 ohm
100v RMS 50 ohm line Load
| |
| |
+--------------+----------------------+
gnd
```

Here's the present example:

```
Rs Vg Vl
+----/\/\/-----+----------------------+
| 50 ohm |
| 1 WL |
Vs 360 degrees 23.5+j44.1
100v RMS 50 ohm line ohm Load
| |
| |
+--------------+----------------------+
gnd
```

If I haven't made some stupid mistake, the conditions at
the source resistor are identical in both examples. But
in the second example, it is obvious that energy can
be stored in the transmission line during part of a cycle
(thus avoiding dissipation at that instant in time) and be
delivered back to the source resistor during another part

of the cycle (to be dissipated at a later instant in time).
That is the nature of interference energy and is exactly
equal to the difference between the two powers that you
calculated. You neglected to take into account the ability
of the network reactance to temporarily store energy and
dissipate it later in time.

All of the reflected energy is dissipated in the source
resistor, just not at the time you thought it should be.

While performing this analysis, you will discover the ability
of superposing waves to redistribute energy (even in the
complete absence of ordinary reflections). Not possible in
the above special case examples, but under other conditions,
the redistribution of energy can attain perpetual steady-state
status (even in the complete absence of ordinary reflections).

There are two mechanisms involved in the re-routing of
steady-state reflected energy back toward the load.

1. Ordinary reflection of single EM waves governed by the
rules of the wave reflection model.

2. A redistribution of reflected energy back toward the
load as a result of superposition of waves accompanied
by an average level of steady-state interference.

Hello,

I will be using a single antenna going to an A/B switch so I can feed the antenna to either one of two Scanners (receive only).

Apparently the switch does Not ground the unused port.

Was wondering if having the scanners antenna input jack just "floating" while the unit is off has the potential for damaging the radio ?

I guess I should also ask the corollary: If the unused scanner is turned On accidentally, and the port is floating as before, any potential liklihood of damage for this case ?

Guess I am worried about static buildups, etc.

Thanks,
Bob

Like Richard says, most antennas are rather like an "open" circuit,
too, in this regard. If you're concerned about static buildup on those
Receive only antenna inputs, you might consider putting a 1M ohm
resistor across the antenna inputs to chassis ground.

I think we can all agree to what would happen in the turn off situation following a long period of stable power flow. When the source voltage steps from 100v to 0v, the power on the transmission line reflects to the 50 ohm source resistor and is all absorbed.

On the other hand, in the case of steady power flow, the source is presented with a reactive load of 73.5 + J44.1 ohms. The reactive part of this load results from returning power from the transmission line.

For the resistor Rs, it will have power applied from two sources, the source and the reflected power from the transmission line, i.e., the source power and reflected power are in series when considered in relationship with the resistor Rs. The problem is that 'what looks like two sources to resistor Rs, is really only one source, Vs'.

I think you are looking for solutions that show how power to Rs peaks at a different time from when power into the transmission line peaks, which is yet a different time from when power from Vs peaks. You are looking for the instantaneous timing of 3 peaks.

No, you're the one who inferred that from what I actually did say, which is (in assorted different wordings) that we're dealing with a linear system, and as such we can fully analyze it and indeed get MORE insight into what's going on by using instantaneous voltages and currents than we can in looking only at averaged powers. Indeed, in setting up the analysis, it matters not a whit what relationship the reverse wave has to the forward wave. There is neither a need nor an advantage to special-case something like coherency; it all falls out of the much more general analysis. There may be interesting things to observe in the outcome of the analysis; that's a different issue.

Note that, as far as I've been able to determine, Michelson did not have a coherent light source to shine into his interferometer, but still he saw interference patterns. Perhaps he had invented lasers but failed to tell the world about them, but I rather doubt it. Carried to something more of an extreme, FTIRs tell you about the spectral content of relatively broadband light, a few octaves, by analyzing the interference pattern produced by a Michelson interferometer. But the instruments and models I can reasonably apply to our slow-as-molasses radio-frequency waves let me get even more insights into what's going on.

As far as I can see, this is all in agreement with what Gene, Roger and Keith, and perhaps some others I haven't been following, have been saying in this thread, and what many others have said for years in this group. If you get the idea that people aren't listening to you, maybe it's because they've heard your story and see no advantage in it over the more general analysis that's readily available.

I have a wonderful old book, named "A Treatise on Optics", written sometime in the late 1800's. I have to look it up here, Perhaps Cecil would be interested in a pdf copy if I locate it again.

Those old boys could do an awful lot that we do today, and I was amazed at the precise measurements that they could do with almost entirely mechanical devices. Coherent light is not the half of it!

We are both more and less advanced than we might think.

Hi Mike,

Coherence has become a shallow rhyming proof rendered as "SoThereIt's!" (a mumbled qed). It is a convenience of a special solution which requires artificial constraints that over the course of "debate" have become necessary correlatives to a general "law" of optics. In fact, few have examined what "coherence" actually means, but instead it has been Xeroxed by Cecil into the argument.

Both Mike and Tom have been able to disconnect this term as one of necessity for monochromaticity (not required) and instantaneity (also not required). This lack of requirement (that requirement having been artificially injected into the discussion) is historically exhibited in work going beyond 100 years old. The first work was with sun/starlight that is neither pulsed nor monochromatic, and yet and all, interference was clearly found which led us to this discussion.

Even though the classic hologram, developed 60 years ago, or so, was originally monochromatic; it didn't take much more effort to accomplish the same photography with white light (1968). Wide band sources can demonstrate interference as readily there as with the original Michelson-Morely interferometer. In fact, most here need only open their wallet to examine a credit card or driver's license to prove this to themselves under a common table lamp.

Coherence (cross-correlating) is a statistical term for comparing (0.00 to 1.00) complex waves. You can have temporal coherence, spacial coherence, spectral coherence and on and on; none of which are actually named here, but whose various definitions have been notoriously cross-connected into a hodge-podge argument of no particular merit.

If we delve into the merits of sun/starlight, we eventually narrow on into the distinction of these terms of spatial and temporal coherence and the coherent area/length/volume (where incoherent sunlight is found to be coherent within 0.02mm) and then into what has already been identified by Gene with partial coherence (a topic that Wolf pursued, and at which Born hesitated).

Fortunately, we amateur radio operators are not concerned
with anything that complex. We are concerned with
essentially single frequency, phase-locked signals in a
single-source, single transmission line, single-load
configuration. Many levels and dimensions of complexity
simply are negligible concerns within the amateur radio
environment. Introducing irrelevant issues is just a
diversion away from ideal examples which are relatively
easy to understand. Isn't it better to clear the waters
rather than muddy them?

And soon, we're going to get radios which use reverse polarity
connectors, because they're more easily available :-)

My replacement antenna for the one I sent away is comming along just
fine
and I will probably be active on the air in a few weeks.
The new one is about two shoe box size and will be connected to a tilt/
scan
mechanism so that I can fully determine all the characteristics in
real life circumstances.
The frequency spread is down to the top of the broadcast band and it
will be controlled by my
Icom where I will disconect the inbuilt tuner motors and reconnect to
my antenna.
This should then ensure that the antenna is always in equilibrium
screw driver style
when I am on the air regardless of the band in use.Hoping to change
polarity in QSO's
to investigate the differences. Hopefully this summer the pan tilt
will also be made
automatic for best polarity reception which will then allow for the
addition of a dish reflector.
Bought myself a new thin Mac laptop which is exciting to use. There is
a free NEC 2
program available(cocoanec) so it is getting difficult to determine
what to work on.
Spring is coming and life is good despite the naysayers.
Have a happy day
Regards

Art

Here is a link to a discussion of AC power. http://en.wikipedia.org/wiki/AC_power

How do you propose to seperate reactive power from reflected power?

I agree, you don't know the difference well enough to differentiate
silt from mud from glacial flour - and yet you offer your fortified
kool-ade. Your food coloring, sugar, and added special ingredients
doesn't bring clarity (and as any nutritionist would say: sugar is
empty calories).

which is why I mentioned:
"Watch out, though, for the assumptions in the constraints"

However, I believe it is incorrect to characterize his analysis as empiricism (i.e. getting experimental data and fitting curves). His analysis (and that of Harrington and Thiele) is entirely theoretical, and actually doesn't deal with loss in the antenna, per se. Indeed, Chu's analysis is based on a simple case (a dipole), but that's more because it's a good first example (and he could use the previous work of Schelkunoff as a starting point). I believe the analysis is generally valid, regardless of what the actual antenna is.

One does, of course, need to operate at a frequency in the ham bands
(some of the 802.11 channels are not in the ham bands...)

Some of the fancier WLAN gear is perfectly ok for Part 15 (with
appropriate antenna) but cannot work as amateur gear (because it
radiates out of the ham band).

You may well be correct. I cannot enter the IEEE papers that you
allude to
to study it furthur. The fact that my impedences are high and the
bandwith is large
is really putting me in a unknown area and I have a lot to learn about
it
Regards
Art

For average power, it's easy using phasors.
real power = V*I*cos(theta)
reactive power = V*I*sin(theta)

I know very little about instantaneous power having
avoided thinking about it for most of my life.

Who knows what "efficiency" represents in the electrical world?
It is the word "small" that confuses everybody when the word
should be" fractional wavelength".
Small and large are meaningles in the antenna world.
No I diddn't overlook the sniping.

To belittle is to inform others of one's own characteristics.
Those who belittle do others a service by showing what they are.

John Kansius is that very interesting individual who discovered a way to "excite" salt water with HF RF and cause saltwater to burn. This URL contains an embedded video on him and his discovery:

http://bobmccarty.com/2007/09/11/researcher-discovers-way-to-burn-salt-water/

Well, he is back in the news!; and, he is now attempting to exploit his discovery as a cure for cancer:

http://www.goerie.com/apps/pbcs.dll/article?AID=/20080310/NEWS02/803100360

Since this is a new field of discovery, amateurs can possibly contribute or even profit from efforts in this field ... the above states he is now working on the equipment to accommodate humans for human trials. Certainly brings to mind an "antenna" to couple the RF field to the body ... who can say where this will all end up?

Can anyone tell me if you change the shape of a given antenna, will it change the chararistics?

I.E.:

I have a 3 element 50 Mhz yagi on a 6 foot boom.

I want to mount the antenna in the back of my pickup-truck and if I bend the elements down the antenna will fit within the confines of the truck (in other words not stick out into the other traffic lanes). Therefore I can still mount the antenna about 8ft off the bed of the trk and to keep it from falling off I can guy it to the trk.

yes, it will change the characteristics (potentially a lot)

You can model it in EZNEC, NEC, etc. and get a feel for how much.

However, gut feel... the elements are about 3 meters long, right? (1/2
of 6 meters. that's about 10 feet? And you want to make the antenna
have elements that are, say, 7-8 feet long?

Assuming you can load the elements appropriately so that electrical
properties work out, the performance of the 3 element yagi with 8 foot
elements in a truck bed will be pretty comparable to the 3 element yagi
with 10 foot elements in a truck bed. If it were 3 dB different, I'd be
surprised. If it were 0.5 dB different, I wouldn't.

either way, the truck body is going to significantly interact, and
that's going to be a big factor.

yes, it will. how much is hard to guess, but i would say probably not as much as mounting it a few feet off a metal truck bed with a cab in front of it.

I think the conventional meaning would be power radiated vs power into the system.

If you define "power radiated" to mean "power radiated in a particular direction" then you're adding directivity into the mix.

If you define "power into the system" to be 120V Wall power that's different than RF power at the feedpoint of the antenna which is different than RF power out at the output of the transmitter.

So, you have to define the appropriate reference plane. The antenna literature tends to draw the boundary at the feedpoint of the antenna, because the rest is "circuit theory".

The ham world tends to draw the boundary at the output of the transmitter (so we include loss in feedlines and matching networks), because the FCC power limit is usually measured at that point. (although nothing in the rules says you can't measure after the matching network)

In the commercial broadcast world, there's a sort of hybrid, because there's an RF power limit AND a requirement to have a particular field strength in the far field at a particular distance.

> It is the word "small" that confuses everybody when the word
> should be" fractional wavelength".

Nope.. small in an absolute sense. An antenna that is 10 times bigger will have more directivity or other figure of merit. Applies pretty much whether you're comparing an antenna that is 0.01 wavelength to 0.1 or comparing one that is 10 wavelengths to one that is 100 wavelengths.

What you can't say is that the amount of change from 0.01 to 0.1 is the same as from 10 to 100.

> Small and large are meaningles in the antenna world.

They have meaning as far as relative. large is better than small.
And, "directive" antennas that are small relative to a wavelength tend
to have high Q (in the stored vs radiated energy sense, which may or may
not imply narrow bandwidth)

It's probably worth finding a library that can get you copies of the
papers, rather than relying on interpretations and summaries. The most
common misinterpretation is to conceptually equate antenna Q to antenna
bandwidth.

Your response is worthy of Charly.

Ohm's Law doesn't work at all scales anyway - but Ohm would have been
resilient enough to have taken it where it needs to go in this day and
age.

<ArthurUnwin@gmail.com> wrote:

Hi Arthur,

Let's see if you can follow the inference of what you claimed to have sought in a reference for the signal strength of an antenna correlated to radiator length. It is a very, very simple example, two wires, no loads, very small:

It takes Laport only 3 pages to name three references for the math (Stratton, Skilling, and Kraus); provide the equation; and directly state at the bottom of page 3:
"directly proportional to the current and to the
continuing on top of page 4:
"length of the doublet..."

No requirement for resonance, no mention of Q, the only resistance is that of free space, nothing about equilibrium, just a straight answer. The math has been confirmed by experiment, and it is duplicated in models that are fully consistent with all scientific enquiry for the past three centuries which exhibit every quality of the math and the quotation above. The text has been made FREELY available here. No need to purchase.

There are no pages with pictures to color, so reading that far can be tough to master for one finding it difficult to search this out:
>>I have searched quite a bit for evidence that states that performance
>>of antennas can be rated by it's size.
"Quite a bit" sets the standard for the whimpering of whipped dog denial. If just a teensy-weensy bit more effort were made, it is obvious the complete investment in antennas the size of a cracker-jacks box would collapse like the home-loan industry.

The question carried with this is:
if an amateur were given the choice between your design, and this simple two wires. then how much would he radiate or perceive any greater signal with your design?

No doubt a very difficult question that will fail to obtain any metrics, and probably not even the grace of a direct answer. It is suitable for troll bait however, and the volume of response will weigh that accordingly. If providing the grist of measurement is so difficult to respond to, why are you here?

>Those who belittle do others a service by showing what they are.
which may already answer my question with your burning bridges at

Hello,

Would you expect to see, in a practical sense, and meaningful difference
between RG6 with a copper plated steel center conductor vs an all copper
one, going from the antenna to a receiving scanner (50 foot run; 1 GHz max).

Tried to find some attenuation tables for this in Google, but had no luck:
Plenty for the coax cables themselves, but might you know of any chart links
that show attenuation for the different types of connectors ?

Thanks,
B.

No.

Connector loss is negligible (<0.1dB) for all reasonable connectors.
The ohmic losses would be a tiny fraction of the ohmic loss in the cable
itself (i.e. the connector interface is a few mm long, compared to
meters of cable).

Skin depth at 1 GHz in copper is 2 microns (0.08 mil). 6.5 microns (.26
mil) at 100 MHz. Your copper clad steel is probably just as good as
solid copper (check the data sheet and see what the clad thickness is..
if it's 4-5 times the skin depth, it's the same as solid.

Also check the shield material (there's more of it, but if it's
aluminum, it's lower conductivity)

At higher frequencies, dielectric loss will be a goodly fraction of the
total cable loss. Again, the connector is very short, so its dielectric
loss is a tiny fraction of the overall cable loss.

There will be no measurable electrical difference between copper clad steel and pure copper center conductor.

There's no mechanism within any common type of RF connector which causes any significant amount of loss. Various types can cause some impedance mismatch, but not enough to cause a noticeable reduction of signal to the receiver.

This doesn't answer your question, but it may give you some
alternative ideas. I think the top link, the Moxon antenna, may
relate somewhat to what you are looking for. The lower link may give
you some "shortened beam" ideas.

I hope you find a solution.

Cecil,

There may be some terminology confusion here.

Maxwell's equations are really the only relevant physical equations
there are to work with, at least in the classical regime. The discussion
about constructive, destructive, superposition, linearity, etc.
represents merely mathematical manipulation of the basic physical
entities embodied in Maxwell's equations.

All of this *math* is of course very important and very useful. However,
it is not a replacement for the *physical* laws known as the Maxwell
equations.

(And we all know that these endless threads are closely parallel to the
blind men describing an elephant puzzle.)

This one is great, and FREE. It will do all the tests, and uses a
random selection of the pool each time.

And in case I forgot to mention, it's FREE.

FREE is good. You'd think all the online tests would be FREE, since the
question pool is public property.

Paul:

Finally responding after a few weeks of being gone.

To answer some questions, the radios are usually operated from 1/2 to 5 miles apart from car to car. It can be flat wide open plains like here in South Dakota or in the mountains with tunnels. I realize results will vary with these differing conditions.

Here is the documentation concerning the NARCOA frequency:
==========
NARCOA has a license and we are authorized to operate under it. NARCOA is licensed for the frequency of 151.625 MHz. The NARCOA call sign is WPHT745. This frequency is in what is known as the VHF-High Land Mobile Radio (LMR) Service band, and uses a modulation known as narrow band (5 kHz deviation) FM. This band is reserved for commercial activity; educational and philanthropic activity; clergyman and ecclesiastical institutions; and for hospitals, clinics and medical institutions. NARCOA's activities are considered to be educational and philanthropic, and fall under Title 47, Part 90.75 of the FCC Rules and Regulations.

151.625 MHz is specifically assigned for itinerant use. That is, stations licensed to this frequency are not restricted to a certain geographical area and the license does not call out specific coordinates for base stations, but mobiles can move about within the United States, depending on the needs of the licensee. This makes the itinerant frequency especially suitable for NARCOA activities. (Note that we are not licensed to use this frequency in Canada or Mexico.) Power is restricted to 110 watts.

It is important to note that NARCOA is not the only licensed user of this frequency. There are many licensees for the itinerant channel ranging from truckers to hunters. FCC rules require that users of this frequency be considerate of other users and to not interfere with

their communications. Each user is responsible for knowing and observing the FCC regulations regarding radio usage on the LMR bands. Each club should keep a current copy of the FCC Code of Federal Regulations, Part 47 available for its membership. This can be obtained from the US Government Printing Office.
==========

Hopefully that will answer the type of license used. I would like an antenna that can be removed while pulling the car down the road. If taller means better reception, that is OK with me. The antennas would be permanently mounted on each car. It wowuld make sense to mount the antenna on the roof of the metal topped car but could be side mounted on the fiberglass car.

Can I purchase the needed antennas from a store and if so, can you recommend one?

Thanks

Dave in Pierre, SD

Mike, I would like more details on building the antennas. I have the skill to do so.

These speeders are getting hard to find but if you look under the for sale link on www.narcoa.com you will see where some are for sale from time to time. They could be purchased for $300 20 years ago, now the same car costs $3,000. Wished I would have bought a 100 of them :-)

Thanks!

John consider this. Water is diamagnetic thus it needs to oxidise for
galaxy particles to settle upon it.so it can radiate. Ofcourse it
cannot oxidise on its own.
So we must look at the salt content. To clean of the junk below the
water line
of a boat one can place current into the water and a electrolysis
action comes about
that cleans the hull of the boat. A electrolytic action can be used to
crack air or water
into its component parts and if the circuit resistance is high then
combustion occurs.

This brings up a problem. If a 1/2 wave antenna was in equilibrium one
should
be able to equate the efficiency
with that of a full wave antenna which is not the same.
If the sequence of actions for a given timeis the same and repeatable
it would be true
but actually you are now comparing apples and oranges in that one is a
closed circuit
and some on this group suggest it is an open circuit and others call
it a series circuit
which is totally different from a tanks circuirt
The underpinnings of Maxwell formula's is that there must be a state
of equilibrium
so the datum must be the efficiency of a tank circuit which is as near
to 100%
efficiency as perpetual motion if without resistance.!
One cannot break down the efficiency of a 2 or 4 stroke engine by
examining the heat /energy
exchange for the total engine by examining what happens during one
revolution alone.

The difference will negligible above about 10Mhz, and even down to 1MHz is not sufficient to be a problem in your receiving application (since it attenuates both band noise and signal, and your reception is probably limited by band noise and/or IMD noise in the scanner).

Did you mean conductors? If so, see above.

If you did mean conductors, some hams flap their jaws about 0.5dB per connector... but their assertions are not bourn out when connectors (that are not defective) are measured.

Since the OP was asking about frequencies up to 1GHz, I would be more
cautious about losses in connectors. Poorly assembled connectors can show
significant losses at 1GHz. Also I have come across connectors and adaptors
(SMA) that show loss for no apparent reason at a Gig or so., now whether
this is due to dielectric losses or some other factor I am not sure but
mechanically they appeared to be prefect. One particular SMA barrel had a
stable and repeatable loss of over 2dB, but was clean and gauged OK.

Some of the cheap PL259 connectors also use very poor dielectric which show
significant loss at even VHF.

I'm surprised at these reports, but not too much except for the 2 dB connector. It must have had some internal corrosion, or perhaps something like a helical internal contact causing an impedance mismatch that would look like loss in a matched measurement system. (Some el crappo UHF barrel adapters have found to be constructed that way.) I've seen some awfully shoddy BNC connectors at ham conventions and wouldn't use them for anything at all critical. But the OP asked if there was a place he could find the losses of various kinds of connectors. I don't believe there's any place you can go to find the losses of shoddily made or improperly assembled connectors or adapters. Decently made and properly assembled connectors of standard types show no appreciable loss at 1 GHz. If loss is a concern, my advice is to buy name brand connectors, and especially avoid the cheap stuff you see at places like flea markets.

I only skimmed a medical journal article about Kansius new endeavour, but I think I got the basics...
It is actually not a just simple use of passing low frequency RF through the body - we all do that when putting power into a dipole strung over the house...
First, they will prepare nanotubules of carbon - very small, the size of viruses and smaller... The size and shape of these tubules is actually very cutting edge technology - and fascinating to an old cellular biologist like me...
Then they will attach the tubules to prepared proteins - i.e. antibodies - that will bind only to the tumor cell proteins and not to the other proteins in the body...
Then this preparation is introduced into the body and allowed to circulate... After a sufficient time period two things will have happened... Some of the prepared nanotube-antibody-particles (NAP) will have entered the malignant cells and been bound in place by antigen-antibody reaction, and the remaining NAP will have been safely cleared from the body fluids via urine, stool, respiration, and sweat - and what remains in circulation will be too dilute to cause problems during the heating phase...
Now, it is show time... An RF field is swept across the body causing the NAP to physically heat up, cauterizing the proteins of the malignant cell resulting in its death...
The real step forward here is making viron sized nanotubules that will respond to a low frequency RF field by heating up... Normally it would take gigacycle frequencies to heat such a small particle, but these frequencies do not penetrate body tissues-water to any significant depth, making them useless in treating deep tumors...
But here, the low frequency will penetrate the entire body mass without causing heating of the non malignant body tissues-water on its own while the tubules inside of the malignant cell respond to the low frequency and heat up...

I don't know who found that they could get the tubules to heat in low frequency RF, Kansius or the team he worked with -but it is the major step forward... I expect a Nobel prize in the future for the team...

Now, as to his making water 'burn'... It was and is nothing but an illusion, a parlour trick, of using RF to electrolyze water into "Brown's gas" and then ignite the hyrdrogen-oxygen causing sodium vapor to glow in the flame - you can do the same using a bunson burner with a lot less effort... However this new use of nanotubules is a major step forward...

Even at 1GHz, I don't believe that you would get as much as 2dB of loss
even if you joined two pieces of coax by stripping the ends with a
knife, twisting the conductors together, and wrapping them in scotch
tape.

Hello,

First, let me say thanks to everyone for the replies and help.
New at this, and it seems these very basic questions of mine keep coming up
the more I look into it.
Great hobby, and really do appreciate the help, very much.
Super newsgroup for folks like me. Sure is a lot to learn re antennas;
reading the ARRL book on it now.

Would like to modify my question somewhat.
Was really surprised to learn about the copper on steel, vs all copper
center conductors on coax.
I thought the difference were only in types of shielding; not center
conductor construction, and that RG6, e.g., was RG6, at least concerning
attenuation and perhaps "quality". Guess not ?

I understand, and am aware of now, the skin effect depth
Will read up on it some more.

Question: any meaningful difference for the sw frequencies; say from 0.5 to
30 MHz ?
I have a sw receiving set also, and frankly, when i strung my coax for it, I
never considered the center conductor coax's construction.

Should I have, possibly ?

Thanks again,
Bob

Hi guys:

I&#65533;ve worked as an engineer in University Physics departments for more than 35 years. At lest 30 years ago I helped a medical researcher at Michigan State University investigate if cancers could be treated by injecting metallic salts into a tumor and heating it with RF (this is were I came in, I had a 50Kw induction heater). Out side of cooking the mouse it didn&#65533;t work well. I work with some of the leaders in nano research and carbon nano devices here at Penn State University and from what I see here this it the dream of someone who almost knows something. I don't think it will work and most likely will do harm.

I was actually replying to W3RV. However, since you piped up...

Have you had any books on the subject published? How about research papers? Anything published at all? Do you have any presentations with equations prepared to support your claim? To which companies have you sold your expertise in this field? Have your taught any classes?

It is laughable to think anybody would consider you an authority on the subject, much less a greater authority than Kraus or any other contributor to this group. You really should get some psychiatric help to quell those delusions of grandeur you have.

Cheers,
John

Well, I hope it will work - but don't hold your breath. Preferential heating of tumors has been around for quite a while using other methods, some a lot less nasty than subjecting a person to major RF intrusion.

By the way John, read the book and determine why he points to a pitch
angle for best results
Thus pitch angle is not at right angles so perhaps you can explain
that. You can't learn just by belittling facts

The items in question were SMA barrel adaptors and as I said showed no signs of damage, corrosion or spreading of the contacts and interface dimensions were in spec

It is surprisingly easy to get significant loss at 1GHz and above, 2dB would be very easy to achieve even when using what appears to be a 'good' connection.

Balanis says, speaking of an infinitesimal dipole:
"Integrating the complex Poynting vector over a closed
sphere, ... results in the power (real and imaginary)
directed in the radial direction. Any transverse
components of power density, ... will not be captured by
the integration even though they are part of the overall
power."

Apparently, Kraus' assertion is a result of the integration
math and does not necessarily correspond to reality.

John, to be fair, in another posting, I quoted Balanis
as saying: "Any transverse components of power density
will not be captured by the [Poynting] integration even
though they are part of the overall power." Balanis seems
to imply that it is possible for transverse radiation
components to exist but get lost inside the math model.

There's one here in Tyler, TX that destroys tumors by
continuously changing the source location and direction
of an EM beam while maintaining a stationary intersection
point at the tumor location. Seems to be getting good
reviews - don't know the frequency.

Do you remember diathermy machines on 11m?

Art, don't know if you have Balanis or not, but on page 134
of "Antenna Theory", 2nd edition, his example of a radiation
vector from an infinitesimal dipole is not perpendicular to
the dipole direction.

I have to admit that I've routinely worked to 870MHz, and recently even
to 1003MHz, but rarely ventured higher. However, I've never found any
excessive loss in a connector which could not be accounted for by a
straightforward 'bad connection', ie usually a total or partial open or
short circuit, whether in the making off of the cable, or in the
construction of the connector itself. Honest!

This has been a standard technique for decades, typically using x-rays or electron beams. It often works effectively for well-defined isolated tumors. However, the standard technique cannot be used for more diffuse cancer. The seek and destroy principle has been the holy grail for a long time, but I have not seen any reports of systematic success. (I have not looked closely.)

The "Tyler" technique has undergone a lot of improvements over the past few years as a result of much better computer control. The problem with the "decades old" approach was that, while the targeting is quite straightforward, and the mechanical motion necessary is achievable, the dose control as a function of beam position was beyond available capability. As the radiation source rotates around the body it is necessary to constantly adjust the energy and dose to get the best result, since in general the tumor is not exactly in the center of a spherical body.

(Eons ago, when I was a grad student, a couple of my office mates worked in this area.)

73,
Gene

3090. MA5V vs. MA5VA

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-11 17:01:43 UTC
From: Javier <javier@invalid.invalid>
Message-ID: <fr6dtnstp1@stationair.kjsl.com>
Source record: 27112

Greetings,

Would anyone care to comment on the differences between the Cushcraft MA5V and MA5VA? At first glance, the "A" version has eight radials instead of eight, and the feedline choke is wound on a ferrite toroid, rather than on a PVC form.

Real world performance differences would be nice to know about...

I haven't got that book but it doesn,t matter. The group will chose to
believe the
books that put it at parallel to the radiator axis. It is easier to
belittle the truth rather than put a radiator at say 12 degrees
to the earth surface and compute for max horizontal radiation. Repeat
but make the radiator parallel.
If the program agrees with you then buy it for future proof. I said
this before Cecil
but this group were frightened to explore for themselves and chose to
belittle instead.
Many were educated by remembering,few checked things out for
themselves.
Same goes for small antennas, they confuse small antennas with
electrically small antennas
big difference. Academia referrs to small electrical antennas when
discussing the subject,
My antenna is NOT electrically small. Period.

What Kanzius (note proper spelling if you plan to Google him) has
RE-discovered is the principle behind what's commonly called
"induction (or inductively) coupled plasma" - ICP for short. The
water is being vaporized and the vapor heated to a high temperature by
the radio waves. In the course of this some water vapor may
disassociate into hydrogen and oxygen and immediately recombine, but
most if not all of what you see is yellow light emitted by highly
excited sodium atoms. If that's what they call "burning water" then I
guess the water is burning, but the water isn't combining with
atmospheric oxygen to burn as gasoline does - for a net release of
energy - which is the implication when they talk about this as a
possible energy source - which is just nonsense. It isn't a source of
energy because whatever energy you get out of this process you have to
put that much into it in the form of radio waves plus much more to
cover some rather large losses... the least of which is the efficiency
of the RF generator. The laws of conservation of mass and energy
always prevail. Power out cannot exceed power in and in the case of
disassociating water it's more like 100% in and 40% out.

Typical ICP plasma temperatures are 6000 degrees and much higher, but
with Kanzius using water as the source of his plasma material (rather
than a gas or a vapor), and using a wick (that's the paper towel) to
increase evaporation, much of the energy in his plasma goes into
evaporating more water and raising the temperature of the resulting
steam. Watch the video again and listen for Kanzius to describe the
bubbles boiling at the top of the water.

See http://en.wikipedia.org/wiki/Inductively_coupled_plasma

Info on Kanzius http://en.wikipedia.org/wiki/John_Kanzius

ICP was around in and before the 60s...

It says human trials are several years off and that's probably optimistic - unless we're talking just parts of humans like hands and feet. If the FDA approves whole body trials that will be about the fastest they've ever moved. Kanzius does seem to be onto something though. The important part - injected nanoparticles that absorb the RF radiation - is mentioned only in passing in the URL immediately above. It strikes me that is the key, not just general exposure to RF.

I'm not taking any position on whether this cancer cure has merit, just commenting.

Cecil,

I did nothing more than supply a quotation from a respected authority on the subject. I did not support the authority. Art dismissed the quotation without so much as a single reference to any other authority. He did not provide any supporting math or technical papers. Isn't this like saying "It is so (or not so) because I said so. Take my word for it."

And he did not answer a single question I asked. Hmmmmmm.

At least you supplied another viewpoint from an authority, although you go on to reduce my confidence in the quote with "seems to imply" and "it is possible" (but not certain).

73,
John

15 years ago I stated that radiation is in the form of pulses,all
laughed
Since then I have itemised the steps to make the small antenna, all
laughed.
The info is in the archives many many times but to my knoweledge
nobody
has tried it for themselves preferring to memorise what the books say.
Yes it does look like a tuned circuit on the end of a coax but what if
it is?
Can you comment on the tilt angle of a radiator to ground to achieve
max
horizontal polarisation? Are you equipped to ascertain the answer for
yourself?
If so then do it and explain it to all, real proof you say. Hams can't
handle theb truth
When the results come out it will prove nothing to this group as they
then will
revert to attack the method of testing or the tester himself. I
already have read

one comment that has attacked the volunteer tester and that is with
just about
zero knoweledge about antennas. How many have come forward to explain
to
others what Gauss meant by equilibrium? How many have asked what
equilibrium means?
If anybody read the instructions on how to make it in the archives and
followed them
then you wouldn't be left guessing
Art

One thing, SMA connectors are rated for 500 connection cycles, I don't know what happens after that, but on test equipment 500 connections might happen fairly fast. I know from experience that SMA is a connector that's easy to put on badly.

Hi all. I'm pondering how to make a 1:1 current-mode balun that will cover a little over 8 octaves. Thankfully, I can guarantee pretty close to a 50 ohm load over that range...20MHz to 6GHz. I have some nice tiny coax to use in making it. To get to the low end, something like 250nH or perhaps even a little less should do OK, but I need to avoid resonances that will mess up the high end. An air-core solenoid coil of about 250nH will have a self-resonance below 1GHz, so that's probably out. Ferrite beads or binocular cores, perhaps? Anyone have practical experience with how they behave in the GHz region? Comments?

Cheers,
Tom

Tom,

We from time to time come across applications where an RF choke is required to be effective over such a wide range. For example, an injector to supply DC on a coax line to an LNB. Perhaps some of the techniques for cascading chokes to extend the frequency range might offer a solution.

I have been playing around with some 1:1 choke balun designs for HF, and one that I tried used a pair of suppression sleeves to synthesise a binocular, see http://www.vk1od.net/balun/G1-1-LF1260/index.htm . The thing that I discovered is that self capacitance is an issue, though I could fit four turns on the cores, the self resonance was quite low (well below 10MHz IIRC). In the case of 3 turns, self resonance around 12MHz isn't a problem.

If I were to try to extend the upper range of this balun, I would try passing the coax exiting the pair of cores through another core (1t), possibly of a lower μ material, possibly a cascade of cores of successively lower μ material.

John, Roy's program is very old and basic, but it is free to use.
This radiation question is also very basic. So for once do something
for yourself
review your results and tell all what is correct or what not is
correct and that includes
Roy's program i.e. is it reliable if it does not concurr with the
books.?

This question can be resolved very easily and very quickly tho Roy has never talked about it.
People on this group consistently avoid testing this out for themselves possibly
because they also distrust NEC programs. If that is the case view the following:
You have two vec tors that represent electrical field and magnetic fields each at 90
degrees to each other which provides a resultant vector at 45 degrees. Now we must consider
the remainig vector that is named "curl". Now something you can guess at.
At what angle must the "curl" vector with reference to the axis of the radiator be placed to verify
the statement of 90 degree radiation as stated in books? Do the books confirm that resultant angle
via mathematics? Note this also inplies that the magnitude of the resultant vector for the
fields is equal to the magn itude of the "curl " vector. Do the books point this out also?
Do the work yourself and learn by it
Art

Hi Tom,

Up to about 1-2 GHz you can use a series of common mode chokes with different turns and different ferrite material and shape of ferrite material. Saying this is easy, but doing requires lots of measurements. The reason is that above the useful frequency range of the ferrite your coil becomes capacitive (with not very low Q factor). That capacitive part may resonate with the inductive part of the higher frequency section (or transmission line effects) and reduce common mode impedance significantly. Some manufacturers claim to have materials that work up to 2 GHz (for example Steward ferrites, now Laird).

When you have some space available, you might cover the upper part (above 1 GHz), with a gradually changing coax to parallel strip construction of about 12 inch or so. The lower part can be done as described above.

I do have some experience with reducing spurious resonance with filling the open spaces with carbon filled foam. It did have effect above about 1.5 GHz (I hoped effect at lower frequency, but that was insignificant).

Good luck with the design,

Wim

No silly mistakes. This number is computed by the spreadsheet at
http://keith.dysart.googlepages.com/generator,line,load,reflection
as 23.529411764706+44.1176470588235j, so you are pretty close.

> But
> in the second example, it is obvious that energy can

> That is the nature of interference energy and is exactly
> equal to the difference between the two powers that you
> calculated. You neglected to take into account the ability
> of the network reactance to temporarily store energy and
> dissipate it later in time.

I don't think I did.

The power delivered by the generator to the line is
Pg(t) = 32 + 68 cos(2wt)
The average power delivered to the line is 32W while
the peak power is 100W towards the load and 36W from
the line to the generator.
The exact same function describes the power delivered
to the line for 12.5 ohm load 45 degree line example,
and the 23.5+44.1j ohm load 360 degree line example.

And if the load was connected directly to the generator,
the same power would be delived directly to the load.

In all cases the power dissipated in the source resistor
is
Prs(t) = 68 + 68 cos(2wt-61.92751306degrees)
This power varies between 0.0W and 136W.

This is true even when the load is connected directly to
the generator without a line to created reflected power.

The power provided by the source is
Ps(t) = 100 + 116.6190379 cos(2wt-30.96375653degrees)
= Prs(t) + Pg(t)
so all of the energy delivered by source is nicely
accounted for. All of the energy dissipated in the
source resistor and delivered to the line originates
in the voltage source.

Looking at the line where it connects to the generator,
we find that the forward power is
Pf.g(t) = 50 + 50cos(2wt)
and the reflected power is
Pr.g(t) = -18 + 18cos(2wt)

Pf.g(t) + Pr.g(t) = 32 + 68cos(2wt)
= Pg(t)

As expected, the sum of the forward and reflected power
at the generator terminals is exactly the power delivered
by the generator to the line.

So you are correct, energy is stored in and returned from
the line on each cycle, but this is the net energy, not
the forward or reflected power since these are both
computed into non-reactive impedances, their respective
voltage and current are always in phase, so their powers
always flow in only one direction.

> All of the reflected energy is dissipated in the source
> resistor, just not at the time you thought it should be.

So as yet, there is no mechanism to explain storage of
reflected power so it can be dissipated at a different
time in the source resistor.

I stand by my contention that the reflected power is not
being dissipated in the source resistor because the
dissipation does not occur at the correct time.

You could convince me to change my contention by locating
the entity that is storing the energy, and showing some
analysis that explains why the amount of the energy
time shift is a function of the magnitude of the
reflected power.

...Keith

Art wrote:
"Can you comment on the tilt angle of the radiator to the ground to achieve max horizontal polarization?"

Vertical radiators over the earth are optimally exactly vertical. Were it not so, broadcasters would use tillted towers.

An excercise I`ve performed countless times is microwave path establishment and optimization. I`ve bolted the tiny dipole feed into the dish selecting horizontal polarization over vertical polarization in most cases.

To establish a path, I set the azimuth using a transit and Coast and Geodetic Survey maps to aim the dish on path. To aim for the horizon as needed for a long path, I simply use a bubble level on the feed horn.

As soon as the signal appears, optimizarion begins by refining azimuth, elevation, and polarization for maximum limiter current in the receiver. Never have I seen any adjustment other than azimuth make any change in the signal received. Parallel antennas at both ends of the path are optimum. The same is true with vertical polarization for what is essentially free-space propagation except for the grazing near the middle of the path.

Tilt as Art implies it is a myth.

Best regards, Richard Harrison, KB5WZI

> time in the source resistor.

Of course there is, Keith. That's what reactances do.
A reactance stores energy during part of the cycle
and gives it back during a different part of the cycle.
The energy stored during part of the cycle is the
destructive interference energy that you are missing
from you equation. It is delivered back during the
next part of the cycle and dissipated 90 degrees
later.

When the signs of the two superposed voltages are opposite,
there is "excess" energy available which is stored in the
transmission line. 90 degrees later, when the voltages
have the same sign thus requiring constructive interference
energy, that "excess" energy is delivered back to the source
resistor to be dissipated.

Since we already know that the interference energy averages
out to zero, the energy imbalance that you discovered is
obviously energy being displaced in time by the reactance
whether it is from a coil or from the transmission line.

Richard, You are living in the past. Learn how to use a computor
then use it to learn for yourself so that you can be a worthwhile
contributor instead of a book parrot. First proove it for your self
then share findings that you obtain for yourself.Ofcourse that isn't
going to happen
since you don't want to learn how to use a computor because you hate
change.
If Roy is a friend of yours ask him to check it out on his computor
program or
ask anybody who has a computor to check it for you before mounting
your podium.
with silly statements. Why can't you do that vector trial have you
forgotten

that ol;d electrical stuff? Does old age give you enough license to
live a continual senior moment
for days at a time?

I can see that words describe a somewhat plausable conjecture,
but to be convincing, a mathematical exposition is needed.

When is the energy stored where? Energy stored in a capacitor,
for example, should correlate with the voltage on the
capacitor. Similarly for current in an inductor.

To be convincing, the various functions of time need to
align appropriately.

So far, the only convincing expressions I have seen
are:
Ps(t) = Prs(t) + Pg(t)
and
Pg(t) = Pf.g(t) + Pr.g(t)
and, of course, all the corresponding voltage and
current functions line up as expected.

To show that the reflected power is dissipated in
the resistor will require the derivation of some
X(t) such that
Prs(t) = 50cos(2wt) + Pr.g(t) + X(t)
and X(t) needs to be in terms of some known
physical quantities of the circuit.

Hi All,

Anyone can do it wrong (come up with 2dB loss), but we would have a
great more deal traffic here if doing it wrong was that common.

I have measured attenuation of near everything from DC to 12GHz at the
standards bench and RG58 with BNCs for a short run (2 to 3 meters)
never presented any problems being wildly imagined here. At the
worst, the connectors (note plural) "might" show 0.2dB mismatch loss -
trivial.

On the other hand, if Jeff is so sure of this 2dB figure, it should
reveal itself in blisters to the fingers for even mild power (100W).
Since this unequivocal evidence is so obviously missing from the
records (or the testimony, as the case may be); then it is very
apparently one of those "someone heard from someone else about their
brother's friend's boss who had a customer who made this claim."

Oh, crap, Cecil! I know they were not Balanis' words.

The point was that you did not need to supply your own interpretation of
Balanis' quote ("seems to imply" and "it is possible"). You could have
simply supplied the quote and left it at that just as I did in my original
post in this thread. The apparent intention of your "guarded words" was to
support your own viewpoint with Balanis' quote.

Cheers,
John

> Yes it does look like a tuned circuit on the end of a coax but what if
> it is?

Actually, if that is what it is, then fine! antennas such as that are perfectly legit. It will almost certainly use the feedline as a large part of the radiator. This antenna bears some resemblance to the Isotron line of antennas. Not for everyone, for sure, but I'm not going to get into a definition war on what comprises a "good" antenna, at least in this case..

But unless there is something new going on - and I don't buy claims of newfangled physics without proofs - especially physics that need to include apparent ability of comprehension on my part, it is another radiating feed line antenna, and not much more.

Keith Dysart wrote:
> To be convincing, the various functions of time need to
> align appropriately.

And one can tell that they indeed do "align appropriately"
just by looking at the graphs of the two voltages. We know
that the average power in the reflected wave is dissipated
in the source resistor. All that is left to understand is
how long the destructive interference energy is stored in
the transmission line before being dissipated in the source
resistor as constructive interference.

Graphing in ASCII is pretty difficult. Let's see if we
can do it with words. Take a piece of transparent film
and draw the forward voltage to scale. Take another piece
of transparent film and draw the reflected voltage to
scale. Now we have graphs of two voltages that can be
varied by phase. In ASCII, the best I can do is:

```
------ ----
/ \ /
/ \ forward voltage /
/_____________\_____________________/_________
\ /
\ /
\ /
------

----------
/ \ reflected voltage
__________/_________________\_____________________
/ \ /
/ \ /
----- ----------
```

For the first 90 degrees of the above graph, the forward voltage
is positive and the reflected voltage is negative. That is
destructive interference so there's an excess of energy that
is stored in the transmission line. For the second 90 degrees,
the forward voltage is positive and the reflected voltage is
positive. That is constructive interference so the excess energy
from the first 90 degrees is sucked back out of the transmission
line and dissipated in the source resistor. Given that the average
reflected energy is dissipated in the source resistor and assuming
we honor the conservation of energy principle, nothing else is
possible.

Art wrote:
"Why can`t you do that vector trial have you forgotten that old
electrical stuff?

Not completely but it serves little purpose in this arena. I admit that being retired for decades requires me at times to search my memory for awhile to retrieve something stored there but that is where the books come in as reminders.

Richard Clark noted that "size counts" appears on page 3 of Ed Laport`s "Radio Antenna Engineering". Richard was right:

"---concerns the field around a very short doublet in free space composed of a straight conductor of length l in which a sinusoidal alternating current of frequency f is flowing. The current is assumed to be uniform throughout the length of this doublet."

The above exerpt is sufficient to show the field around a very short (elementary) doublet in free space is a function of length l as previously reported from page 864 of Terman`s 1955 opus. The old masters agree. So call me a parrot already. I don`t care.

I gave you examples of my experience with microwaves. These showed antennas with the same polarizatiions have the least path loss. Polarization diversity in addition to space and frequency diversity has been used to improve reception and reliability on mivrowave paths. When one polarization, position, or frequency falters, a switch is automatically made to the other alternative. Reliability is greatly improved. Surely other readers have had similar experiences with antenna alignment to receive the best signal. It requires that the antennas be parallel. Crossed antenna polarization on line-of-sight paths causes huge (30 dB?) loss.

FM broadcasting began with horizontally polarized antennas. Automobiles using vertically polarized antennas required FM broadcasters to add vertical polarization to serve a mobile audience.

Best regards, Richard Harrison, KB5WZI

Any quality coax will have a sufficiently thick copper coating on the center conductor to insure that the current is, for practical purposes, always in the copper rather than the steel down to quite a low frequency. If the plating were unusually thin, the current would penetrate into the steel at lower frequencies and the loss would be much greater. However, loss in a transmission line used for receiving only becomes very much less important at HF and below (that is, below about 30 MHz). So the bottom line is that it's not normally anything you need to worry about.

A copper plated steel conductor is used to increase the physical strength of the cable, particularly cables of smaller diameter and higher impedance, where the diameter of the center conductor becomes small. When done properly (as it usually is), it works just the same electrically as a solid copper conductor.

The _ARRL Antenna Book_ is a very good place to start in learning about antennas.

Hi,

So I've spent months, rather years, carefully designing a new 5 band cubical quad for myself. I've always known that I would use #12 solid copper wire (not stranded), so that is what I used when running NEC2 to optimize this touchy antenna design (over millions of iterations).

Well, real world things are starting to happen. For wire, I've decided what I would like to use is an enameled coated copperweld wire. I'll buy the plain copperweld wire and coat it myself.

So my question is, what is the most accurate way to make sure when I build the quad that I account for the velocity factor (unknown) of the wire I use? Should I grid dip the elements and make sure they agree with my NEC2 model? Can I build a simple loop on a higher frequency with the wire and then somehow use that information to rescale my wire lengths? What is the "right" way to do this? I wonder how consistent velocity factor will be if I do my own coating on the wire....maybe hand coating is a bad idea for this reason....

I spent a lot of time designing a Yagi with NEC2. I used Leeson's correction for taper elements and to calculate the effect of the element to boom mounts. All that attention paid off - I thought my Yagi lived up to the NEC2 predictions very well.

-Scott, WU2X

3120. Re: Antenna physical size

Newsgroup: rec.radio.amateur.antenna

Source record: 27143

I'm a little concerned about the authoritative quotes I've seen lately which state that the field from a conductor is directly proportional to the current in the conductor. While true, it's seemingly being used to support the conclusion that a longer conductor inherently produces a greater field, and by extension, that a larger antenna fundamentally radiates more than a smaller one. Those conclusions are false, and I'll explain why.

It's useful to start with the law of conservation of energy. If an antenna is lossless, then all the power fed to it must be radiated. This has to be true regardless of the antenna's size. So how can this be, if the field is proportional to the conductor length? Are longer conductors less lossy than short ones?

No, the principle of field being proportional to current and conductor length assumes zero loss, so it has to apply to small and large antennas alike. But so does the law of conservation of energy.

The answer to this apparent dilemma is that if you put a fixed *power* into dipoles, say, of various lengths, the current will increase as the antenna gets shorter. This keeps the product of length X current essentially constant, resulting in a nearly constant radiated field for a fixed power input. Another way of expressing the same thing which might be more familiar is that the radiation resistance decreases as the antenna gets shorter. Consequently, the current increases for a given power input. To look at it yet another way, consider that if all the power is to be radiated by both a short and long antenna, the current must be much higher to get the same radiation from a short conductor as a long one.

This increase in current becomes dramatic when the antenna gets very small (in terms of wavelength), and that's where one of the problems lies with short antennas. The I^2 * R conductor loss can become not only significant but large even with very good conductors, when the antenna is small. And that's why small antennas are often less efficient than larger ones. It turns out to be due to the fact that the field is proportional to the current and conductor length but not for the simplistic reasons being implied. But the poor efficiency of a small antenna is a practical matter which can be mitigated, often to a very great extent, by using large and good conductors for example. It's not due to any fundamental rule of radiation.

Another reason that looking only at the current - length rule for field strength can be misleading is that the radiated field is the sum of many incremental fields from the various parts of the antenna. Some antennas, such as small loops or a W8JK beam, create fields which fully or

partially cancel in all directions. So the fields generated by the individual parts of the antennas are greater than they'd otherwise need to be in order to generate the resulting total radiation field. This further reduces the efficiency of these antenna types, since higher currents are being required to generate the larger fields. Still, though, the law of conservation of energy applies -- except for power lost to heating, all the power applied ends up in the radiated field, even if it takes a much larger local (near) field in order to produce it.

There are other consequences of making an antenna small. One is that if you do succeed in making it efficient by keeping loss very low, the bandwidth will be very narrow. Another is that the very small radiation resistance is accompanied by a very high feedpoint reactance. Any practical network used to match this to the common 50 + j0 ohms required by most transmitters and receivers will also be likely to be quite lossy due to very high currents and/or voltages within the network. And, like the antenna, most reasonably efficient matching networks will tend to be very narrowbanded when being required to effect such an extreme impedance transformation.

The considerations above are why small antennas are invariably narrowbanded, inefficient, or both, and if the matching network loss is included in the efficiency calculation, virtually never very efficient. Claims to the contrary are heard all the time. But under scrutiny and controlled test conditions, they don't fare any better than water dowsing.

Hi Scott,

This sounds like a good solution, but you don't state the limits of accuracy you've painfully sought to achieve. I'm not sure about the reference to a million iterations (which would certainly suggest the erosion of accuracy through accumulating rounding errors).

However, GDOs don't suggest precision to me. Yes, you can measure the frequency to a jillion places, but can you find the null to the same resolution? Meters are not all that resolving unless you've got them in a bridge.

>Can I build a simple loop on a higher frequency
>with the wire and then somehow use that information to rescale my wire

Sure, but you seem to inform yourself about the difficulty with the prescient questions that follow:

>What is the "right" way to do this? I wonder how consistent
>velocity factor will be if I do my own coating on the wire....maybe
>hand coating is a bad idea for this reason....

I would first ask why you are coating them at all?.

If I might anticipate because the copper oxidizes and presents a high resistance to current, I would point out that enamel is even more resistive and the current isn't going to travel through it either (the current will travel through the proverbial path of least resistance - under the coating of resistive layer covering no matter what it is composed of).

> Richard Clark, KB7QHC

Well let me put you right Richard, there was no high power, so burnt fingers, this was noticed in a test set-up on a network analyser, and subsequently the adaptors in question were tested in isolation. 'Good' adaptors were also substituted and their loss was measured and was very low indeed.

The problem was first noticed by a very senior consultant in the lab in question and then checked by several other people because they could not believe it either. The connector interfaces were checked and were Ok. No further time was spent investigating why the problem occurred, just 2 SMA adaptors in the bin and the rest of the adaptors in the lab checked.

So please don't denigrate other people's comment without asking about the facts.

My comments were not about properly made connectors, that will have very low loss, but were a caution that at high UHF and above care has to be taken and it is very easy to introduce loss. This is particularly the case when launching from connectors onto pc boards with microstrip or joining on to coax cable.

Having been involved professionally for over 10 years in the design of microwave equipment I can assure you that there is an endless list of the ways that loss can creep into a system at high frequencies.

Actually, we have shown that that is not the case. If the
instantaneous power is not dissipated in the source resistor,
then neither is the average of the instantaneous power. And
we have shown that the instantaneous power is not dissipated
in the source resistor.

You might like to visit
http://keith.dysart.googlepages.com/radio6
for a graph that shows the actual power dissipated in the
source resistor along with the power in the reflected
wave. It can be visually seen that the power dissipated in
the source resistor has no relationship to the sum of the
reflected power and the power that would be dissipated in
the source resistor if there was no reflection.

You have shown that for some of the time energy is delivered to
the line and sometimes it returns energy. This is
Pg(t) = 32 + 68cos(2wt)
which has nothing to do with reflected wave energy dissipated in
the source resistor.

Pg(t) is equal, however, to Pf.g(t) + Pr.g(t).

> Given that the average
> reflected energy is dissipated in the source resistor and assuming
> we honor the conservation of energy principle, nothing else is
> possible.

But the premise in the above sentence (average reflected energy is
dissipated in the source resistor) is wrong, so the conclusion
(nothing else is possible) is as well.

In the HF/VHF range the attenuation should be about the same as an
all copper center conductor. But, if you are running DC or low freq
AC through the coax to operate switching relays or a preamp, the
resistance of the copper coated center conductor is much higher than
an all copper conductor.

I sense a communication problem here.

"Loss" usually implies dissipation of some of the desired power in the form of heat, and that's the way I use the term.

However, people who spend a lot of time in a test equipment environment often use the term to mean loss as described above, "mismatch loss", or some combination of the two. And I've often seen people mistake "mismatch loss" for dissipative loss. But it's important to separate the two, since they have different causes and cures.

Dissipative loss is caused by current flowing through a resistance, which causes power in the amount of I^2 * R being lost as heat. When dealing with dielectric loss, it's often easier to calculate it as V^2 / R. The mechanism is somewhat different but the end result, dissipation, is the same.

"Mismatch loss" is entirely different, although someone making measurements with a network analyzer or other test system won't readily be able to distinguish it from dissipative loss. "Mismatch loss" works like this:

Suppose we have a signal generator with a 50 ohm fixed resistive output impedance which delivers 1 watt to a resistive 50 ohm load. If we were to insert, say, an inductor with a reactance of 100 ohms in series between the source and load, only 500 mW will be delivered to the 50 ohm load. Now, this is for a lossless inductor, so there's no dissipative loss in the inductor. Yet the inductor is said to have an "insertion loss" of 10 * log(1/0..5) ~ 3 dB because the amount of power delivered to the load is less than the amount which would be delivered under matched conditions. Consider another example -- a perfect, lossless transformer is inserted between the generator and 50 ohm load. If the transformer has a 2:1 turns ratio (4:1 impedance ratio), 640 mW will be delivered to the 50 ohm load. So the transformer is said to have an

"insertion loss" of ~ 1.9 dB.

The way to reduce dissipative loss is to reduce the I^2 * R or V^2 / R product one way or another. Power companies do this by raising the voltage for long distance transmission, thereby reducing I. We often use a larger diameter coaxial feedline, which reduces the conductor R -- or use an open wire line which reduces I because of its higher characteristic impedance.

"Mismatch loss" can be eliminated entirely by adding an impedance matching network. In the examples above, a matching network anywhere between the generator and load which causes the generator to see 50 ohms resistive will reduce the "mismatch loss" to zero -- that is, it will raise the power in the load resistor back to its maximum possible value of 1 watt.

Now when Jeff says that loss can be introduced by coax-to-microstrip transitions, he's speaking of "mismatch loss", not dissipative loss. There's no mechanism which would cause the I, V, or R to become high enough in the region of a transition to cause an appreciable amount of dissipative loss. It is, however, extremely difficult to make a transition which doesn't introduce a different impedance in the transition region. (And it's very nearly always a higher, or inductive, impedance due to the fields escaping or fringing from the regions immediately between the conductors.) I'm very familiar with this, having designed transitions which had to maintain the proper impedance from DC into the tens of GHz for very sensitive time domain equipment. It can, however, usually be compensated by introducing complementary impedances in the immediate vicinity -- this is the equivalent to providing an impedance match. The result is a clean transition with negligible loss -- "mismatch" or otherwise. It's not possible to compensate for dissipative loss in this way. If such a transition shows loss in a network analyzer measurement, for example, it's almost surely "mismatch loss" and not dissipative loss. It won't burn anyone's fingers if a kW is applied, and the cure wouldn't help dissipative loss at all.

"Mismatch loss" is useful mostly to people who have to stay in a fixed 50 ohm environment with no opportunity to apply impedance matching. That's not usually the case in amateur antenna systems. So when someone, especially someone with a test laboratory background, says "loss", it's important to ask whether they mean dissipative loss or "mismatch loss", since we can make the latter disappear but not the former.

So, I'll ask: Was the 2 dB connector loss dissipative (caused by an exceptionally high resistance series conductor and/or exceptionally lossy dielectric), or was it "mismatch loss" (caused by a dramatic impedance change within the connector due to a changed relationship between conductors -- say, missing dielectric or something like a helical conductor)?

I go along with that but only if you meant electrically small
antennas.
Some of the group confuse electrically small with physically small.
Richard for years has viewed them as being the same despite my
corrections.
Fractional wavelength is electrically small tho some would say it must
be
less than 0.1 WL

A good question Roy, but I cannot answer it, other than to say that the SMA interfaces were clean and apparently dimensionally in spec.. There was not the time or money to investigate further, the adaptors just went in the bin! (they were good quality adaptors by the way, probably MA/com).

I think I would spend the extra money and buy copper wire. One nick in your
coating and the copper surface and the wire will disappear. If you must use
copperweld, try The Wireman or The RF Connection for copperweld that has a
high density black polyethylene jacket.

I would hate to spend all the time to design and build a quad and then have
the wire be the weakest link.

The difference in your energy levels is in the reactance.
The reactance stores energy and delivers it later. Why
are you having so much trouble with that age-old concept?
The reflected energy that is not dissipated in the source
resistor at time 't' is stored in the reactance and dissipated
90 degrees later. Until you choose to account for that time
delay, your energy equations are not going to balance.

Your equations would be valid only if there were no reactance
and no delays in the network. The lumped circuit model strikes
again.

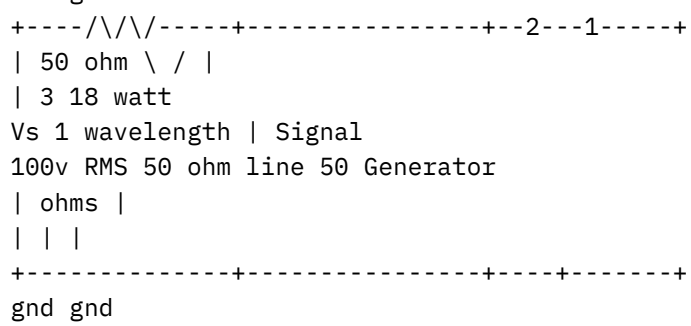
Actually, we have shown exactly the opposite. Maybe a
different example will help. We are going to replace
the 23.5+j44.1 ohm load with a *phase-locked* signal
generator equipped with a circulator and 50 ohm load.
The signal generator supplies 18 watts back to the
original source and dissipates all of the incident
power of 50 watts, i.e. all of the forward power from
the original source. The original source sees
exactly the same 23.5+j44.1 ohms as a load.



The conditions at the original source are identical.
The circulator load resistor is dissipating the 50 watts
of forward power supplied by the original source. The
signal generator is sourcing 18 watts.

Your instantaneous power equations have not changed.
Are you going to try to tell us that the 18 watts from
the signal generator are not dissipated in Rs???? If
not in Rs, where????

On a more serious note,
you consistently refer to heating problems or
feed line radiation. Will you be good enough to explain what creates
these
functions and why you can thus refer to them as my problems?
To put things in order.
My antenna does not require a ground system
Electrical WL is alwaysa WL or more in length.
Measurements at the antenna are devoid of reactance at the point of
resonance
Measurements at the transmitter is the same.
Movement away from resonance supplies reactance.
Conformance with Maxwells laws are adhered to.
Now all these facts have been stated many times before, yet you repeat
your views so the actions that create feedline radiation and antenna
melting
problems are totally different to what I understand.

When moving away from the resonant point it provides reactance in
addition to the resistance
All frequencies have more than one resonant point

(I am addressing more than one post with this response)

Basically I want to use copperweld for durability. Its not a matter of saving money over hard drawn copper. I have no experience with (bare) copperweld, but I have read that if you get a nick in the copper layer, basically the steel will start rusting away at that point (very quickly). So I don't have problem using some enamel to protect it (and have done this in the past with hard drawn). I am using copperweld/ insulated wire for my low band antennas - but anyone who has actually built a quad knows insulated wire is much too heavy, esp. when you are dealing with 5 bands.

I have used hard drawn copper with enamel on it on 10 meters and never had a problem with a wire breaking in 10 years. So, I am not really sure if I need copperweld, but I have no expierence with larger quad loops. The goal is to have this thing be reliable.

Regardless still - whatever I wire I use - even if it was bare #12 solid copper wire, I still want to go through the exercise of getting the wire I actually used in sync with my model. So, I'd rather focus the conversation on that topic.

With respect to manually tuning the quad (reflector) after its up, yes, that seems to be the conventional wisdom. How practical and possible is that for me? Mine will sit on 72' US Tower crankup/tilt over - short of renting some huge bucket/boom, I can't see myself manually tuning it when its up. The best I will do is take some type of field measurements and see if it displays anything close to the pattern NEC2 predicts - or better yet, just see if I am happy with it as is. I did not have to make any adjustments to the monoband yagi that went right from NEC2 to the tower, so, I am hoping for the same good fortune.

Scott, you are introducing sharp corners to your new antenna so NEC
will stray from accuracy.

Is NEC4 better in this regard?

Here is the NEC2 reported performance of my current design. Its a 24 foot boom, with 5 bands. 4 elements on 15-10 and 3 elements on 20-17. Optimization is for F/R around mid-band and bandwidth (under 2.5:1 at edges).

http://remote.wu2x.com:8888/WU2X/

Click each <band>.html file to see the graphs on each band. The non-active driven elements are shorted.

Here is the stock Cubex 4 element quad, which is 4 elements on all bands (on a 24' boom).

I would suggest that you check with what Cebik says about it.
At the same time you are also now dealing with vertcal polarisation
which also has a lot of characteristics that are different from planar
yagis where the elements are not in equilibrrium as compared to a quad
design.
One can discharge corona where the other doesn't soto use the same
calculations
for designs that behave differently raises a lot of questions besides
the sharp corners.
Niether of the programs are perfect but better than shooting in the
dark.

Hi Scott,

For tuning, one established technique is to get it up high enough off the ground, pointed up, so that it is not affected by ground too much, but still accessible by a ladder.

As for checking actual performance, note that in all practicality you lack the means to measure the full 3 dimensional performance. Further, even monitoring out 10 miles still puts you below the horizon, and for HF that is barely more than a correlative, as nearly every NEC tool shows performance above the horizon when it comes to the radiation lobe characteristics. Otherwise you would need a helicopter....

You can measure against beacons, but now you toss in the variable of propagation and you would have to marry the NEC output to WINCAP and perform several dozen tests each day over the course of a month or two. IF YOU ARE TALKING PRECISION AND ACCURACY.

On the other hand, you've already validated your testing, modeling, and performance to your efforts for one band - Trust your tools and data to be able to extrapolate it.

I've encountered (defective or broken) SMA hardware that has remarkably
high *apparent* loss. Typically, internal cracks or voids. I had a
batch of Pasternack right angle M-F elbows that had losses that were all

over the place at 1 GHz sorts of frequencies. I'm pretty sure that internally, there was something not connected, or a spring loaded something that wasn't making contact.

In this case, the connector wasn't actually lossy, but more of an extreme mismatch, and when hooked up with a 50 ohm signal generator on one side and a 50 ohm power meter on the other, it looked like loss. Actually, it was reflecting the power back to the source.

In this scenario, with 100W, your fingers wouldn't have gotten burned (but the signal generator would probably shut down with reverse power warnings)

Neither NEC-2 nor NEC-4 has any problem in this regard. Art's statement
is incorrect as quoted.

>So please don't denigrate other people's comment without asking about the
>facts.

Hi Jeff,

Well, in fact, facts were preciously few and generalities were liberally asserted. I read facts attesting to "significant loss" and indicated that it should be attended by heat where in my experience (and as the head of an RF metrology lab) these connector issues far more commonly exhibit mismatch loss (and I chose my words with care) not "significant loss." Bird Wattmeter connectors suffer from this very problem and I have outlined that in the past.

Bob asked about receive properties and RG6 where BNC or N applications would be typically found for operation above 150 MHz. My response with respect to cables (plural) of a short length and terminated with on-par connectors (plural) indicate that loss (insertion loss both as dissipative and mismatch) is principally invested in the cable, not the connector. RCA or F or PL types are not taken seriously in the real world - but they would work suitably for receive. My personal limitation to 2 or 3 meter lengths were for jumpers application. My personal limitation to 1GHz for BNC was for leakage issues, not loss. BNCs/TNCs are rated to 4GHz and N higher to 12GHz. Bob can then research cable which has far more specification available on the web. Abstracting a one-off problem with a barrel connector into general cautions about issues of dielectric quality brings to mind that one data point does not denote a trend. An SMA/RG6 combination is not one that springs automatically to mind; neither does an SMA/50 foot line (presumably RG174 - even though I would do it in spite of demurring it as a solution).

For 50 feet, and considering the receiver and the service, and the link budget, none of this probably matters (not even 2dB). If this is for EME, then yes, it matters a lot. Bob didn't indicate EME.

Hi Jim,

Modifiers abound, and such an abundance generally suggest there are
problems of understanding. Roy and I have already written to that
matter.

Returning to poor connectors, the cables that I gathered for jumpers
at the RF bench were selected, naturally. We had plenty to choose
from, but there were always poor performers for any of a number of
reasons we didn't care to investigate, simply because we tossed the
losers. Insertion loss was never a problem as long as it was
constant. The losers did not present a constant insertion loss which
could have been attributal to connector quality (or construction
quality); but some times there seemed to be the suggestion of
triboelectric effect (cable bending not associated with straining the
connector). Anyway, the cables were tossed without too much regard
for why - we had better things to do (the in shelves never seem to
empty).

That really is good news. Capacitive coupling between close spaced
wires,
progressive change in capacitive coupling to ground from a
verticle ,or wires
at different spacings and closeness must be a devil to calculate tho I
suppose you can also
insert fudge factors for alignment from impirical results which I
presume is the reason
for program modifications despite the inflexibility to change of
Maxwells laws.
Well you highlight one of the answers the gentleman was asking for so
a forthcoming
complete answer from you should give him closure on this subject
Art.

tedious, but not complex. Like all Finite Element approaches, you basically break the problem up into little tiny chunks and rigorously apply basic laws of physics. Charge is charge.

The challenge is not in the theory of operation, but in the practical implementation.

There's also the practical implementation detail of taking a high level description of something and turning it into many, many smaller pieces. (For instance, turning an arbitrary 3-d shape into lots of little plane triangles or quadrilaterals). You want a small number of pieces so the computational work is less (many of these techniques have "work" that goes as the cube of the number of pieces, so going from 10 segments to 100 segments takes 1000 times as much computation), but also you want the pieces small enough that they approximate the original continuous curve to an adequate level of accuracy (the calculus problem)

As you make the chunks smaller, round off errors and numerical precision become a bigger issue (e.g. on a computer with finite precision, summing a million millionths might not equal one). So even if you have a 1000 processor Beowulf cluster, it might not help.

tho I
> suppose you can also
> insert fudge factors for alignment from impirical results which I
> presume is the reason
> for program modifications despite the inflexibility to change of
> Maxwells laws.

No fudge factors in NEC. What changes there are between versions do
things like:

handle insulated wires, or wires embedded in a medium other than free
space. If you accept the constraint of uninsulated wires in a vacuum,
you can simplify the equations, which takes less computation (i.e. you
don't have to take epsilonr or sigma into account). Since air is pretty
close to a vacuum, and most people build antennas out of uninsulated
wires, the first version of NEC did the easy case.

better approximations of the charge distribution on the segment from a
numerical analysis standpoint. i.e. rather than using sin(x) for values
of x near pi/2, where small changes in x result in very small changes in
sin(x), you use 1-cos(x). You could have also just used a zillion
digit sin calculation, but that gets back to the computational
efficiency thing.

More accurate calculations of the interaction between chunks. NEC
essentially calculates the coupling between every possible pair of
segments in your model. Calculating coupling between two segments some
distance apart assuming the segment is very much smaller in diameter
than the spacing and where they are parallel is fairly straightforward.
Calculating coupling between two conductors of diameter d, separated
by a distance close to d, with them at an angle, is a bit tougher. (a
lot of it is back to the issue of precision of trig functions)

Easier ways to define a model. NEC4 includes a function to enter a wire
with a catenary curve. For NEC2, you'd have to do that outside, and
then enter the wire as a series of smaller wires.

There's a readily available paper out there that explains all the
improvements from NEC2 to the later versions, and how they were
experimentally validated.

Abstract

Capabilities of the antenna modeling code NEC are reviewed and results are presented to illustrate typical applications. Recent developments are discussed that will improve accuracy in modeling electrically small antennas, stepped-radius wires and junctions of tightly coupled wires, and also a new capability for modeling insulated wires in air or earth is described. These advances will be included in a future release of NEC, while for now the results serve to illustrate limitations of the present code. NEC results are compared with independent analytical and numerical solutions and measurements to validate the model for wires near ground and for insulated wires.

Jim, that was a comprehensive answer for the gen tleman. Probably more
information
that he can deal with.Seems like it is quite easy to have a yagi
behave when using NEC2
but I still hear stories of the diffuculty of tuning them after
following the nec2 instructions.
Never had a quad before so I am really out in left field on that one

You might have me mixed up with someone else, Art. I have commented on feedline radiation in this context, but my only posts about heating problems was with that antenna produced by the U of Delaware in which the initial press release touted that the original antenna was so efficient that it burnt up when 100 watts was applied. Subsequently removed from later text. I don't think that many people would believe that an antenna that melts is radiating efficiently. Otherwise I only predict that your feedline likely will radiate, not that it will heat.

Sigh... would you like to point out the post(s) where I said all this?

Aside from that, I expect the feedline to radiate.

Well I may have mixed people up. Sorry about that.
What will cause the feedline to radiate given the facts I have
provided?

The last time I read any of Art's postings, he was using AO, which is MININEC-based. MININEC has a number of peculiarities due to choices made in its implementation, including problems with close spaced parallel wires, wires connected at an angle, and very simplified ground model. (See "MININEC: The Other Edge of the Sword", _QST_, Feb. 1991 for more detail.) NEC-2 and NEC-4 also have peculiarities due to their implementations, but ones which are different from MININEC and in some cases from each other.

Hi All

I have built the circuit on this website

http://braincambre500.freeservers.com/rss(1)(1)(1).htm

and the circuit diagram is here:

http://braincambre500.freeservers.com/rss%20schematic.gif

My question is this:

When I increase the antenna length to say 30cms, from the recommeded 6inchs or 15cms, the circuit does not work. Why is this? I know the antenna captures RF signals and this current is fed into the circuit, but I dont know why the circuit stops working - is it something to do with overloading the circuit ?

Thanks for your time
Shelton.

Scott, WU2X wrote:
"I`ve always known that I would use #12 solid copper wire (not stranded) so that is what I used when running NEC2 to optimize this touchy antenna design (over millions of iterations).

Bill Orr, W6SAI devotes Chapter 9 in "All About Cubical Quad Antennas" to tuning and adjustment.

John Devoldere, ON4UN wrote on page 13-52 of the 2nd edition of "Low-Band DXing:
"I designed the quad (for 80-m) with two quad loops of identical length (for a 2 mm OD conductor or no.12 wire).

William I.(Bill)Orr, W6SAI wrote on page 77 of the 2nd edition of "All About Cubical Quad Antennas";
'the individual gamma devices are made of #12 solid copper wire and a small variable capacitor."

Ed Laport pictures a Wind Turbine Company insulator used for two wire balanced lines on page 485 of "Radio Antenna engineering". These were used in WW-2 Signal Corps fhombic antenna kits to support the 600-ohm feedline. The wire was a cable made from (3) #12 twisted Copperweld wires. This same cable also was used to make the rhombic curtain which contained (3) of these Copperweld cables. I used many miles of this cable and never saw a breakage in normal use despite years of aging in all weather and the fact that we were using 100 KW in an antenna kit designed for 5 KW. We did redesign the stainless steel dissipation lines to withstand the high power. With new dissipation lines installed we got many letters of complaint from South America from listeners who had benefited from our bidirectional antennas which were intended to cover central Europe only. Too bad, but other broadcasters claimed the target area we were temporarily occupying in South America.

Best regards, Richard Harrison, KB5WZI

The device is a super-regenerative receiver. The antenna
is part of the oscillator circuit. If you change the
length of the antenna, you change the resonant frequency
and/or possibly cause the oscillator to stop oscillating.
Either of those results will cause the receiver not to
work right.

Thanks.

Recent advances, dated 1989.

What's been going on during the 18 years since then? Polishing NEC-4,
and developing other codes for specialized purposes, presumably. I
know it's a big question, but maybe somebody here can tell us
something.

Ok, so I guess my subject line might have open the door to this discussion. So NEC4 can model insulated wire, which seems like it might be helpful for me. I see the price is down to 300$ now for US non-commercial. Now if I can just get them to answer my email. So what is included in the package - its not listed on the LLNL website. Does NEC4 use the same input deck as NEC2? I assume there are maybe some more input cards? What about the output?

I wrote my own cubical quad optimizing software that reads and writes to the NEC2 input deck and reads the output directly - hopefully it wouldn't require to much change to adapt it to use a NEC4 engine instead.

That's about it. NEC-4 is sort of about as good as you can get for a
"wires" based MoM code. The math isn't changing, the implementation does
the math, etc.

These days, it's other modeling techniques that are being developed:
various FDTD schemes
various voxel based schemes
all manner of harmonic balance

lots of work on automatic meshing (i.e., take the mechanical solid model
from Unigraphics or Pro/E or Solidworks or whatever and turn it into
something that a EM code can process)

yes.. input is basically the same as NEC2, as is the output. A few new
cards (catenaries, for instance)

A well known way to achieve wide bandwidth is to introduce loss. It appears that's what is being done here. Because many amateurs use much more power than necessary, quite a few people find that the reduced signal from the B & W resistance-loaded folded dipole is a worthwhile trade for increased bandwidth. I'm sure that some will be happy with a similar trade with this antenna. Whether you would or not is up to you.

I believe you'll find it to be very poor on the lower bands unless you have a very good ground system.

With a few exceptions, NEC-4 and NEC-2 have the same input and output format. NEC-4 has some additional 'card' types, such as the one for wire insulation.

EZNEC programs can also model insulated wire. EZNEC+ is able to import the wire coordinates (GW 'cards') from an NEC file.

Remember that I do not have all the facts here. There are certainly
assertions. One of the "problems" with scientific inquiry is that it
helps to have an actual device to test. There appears to be one device

(two maybe? and it is in the hands of a snowbound ham in the great north. I really want to see the test results.

So I just don't know. I trust that you would expect no less from me. I have to go on the limited description, and that description sounds like the tuned circuit on the end of coax, giving rise to an unbalanced condition, from there, we can expect feedline radiation.

I understand your frustration Art. I have some of my own. I've asked twice now for a test protocol, and gotten nothing.

I'm hoping that a test protocol is not asking too much...

How can calculate radiation resistance? resistance at 7MHz is
skin effect
http://circuitcalculator.com/wordpress/2007/06/18/skin-effect-calculator/
0.028mm.
for copper pipe 15mm in diameter:
octave:1> 15*3.14*0.028
ans = 1.3188mm^2

0.0155Om/m * 3.14m
ans = 0.048670 Om.
I think it's not bad.

> even counting the relatively low Q of varactor diodes, you'll have

I don't think we have the right to ask him anything.
He volunteered to do it and I accepted
If he answered everything on this net it would start a lot of insults
again.
He has offered to do it for me not the group.
He can make any furthur descisions after that
So we must all be patient and let him do things how he wants after
which you can ask him anything
where he may chose to answer or not.
He has been an observer for a long while and has tried to curtail the
insults
that have gone around these past few years and contrary to others is
willing to pursue
anything that may profit ham radio and not retard it because of
dislike of change.
We are fortunate that there are people around that do not have to add
insults
to their expertise to get the ears and attention of fellow hams
He deserves our respect.
Art
Regard
Art

Sorry.

Hello all.
I'm looking how to make narrow band active antenna for 7 or 10.1mzh.
My idea: I will use magnetic antenna with one loop. A one-turn loop of
3.14m cupper pipe with diameter 15mm has 2.687uH. With Varicaps of
192pf it will have resonance frequency of 7MHz. I will load this LC
tank directly to Gate one of dual gate MOSFET.
http://homepage.eircom.net/%257Eei9gq/rx_circ.html
http://homepage.eircom.net/%257Eei9gq/mosifamp.GIF
Should it work? I'll never seen such schematics. Usually people use
transformers. But I will place this transistor directly inside gap in
the loop of cupper pipe. The Gate of MOSFET will add only additional
2pf to Varicaps and it will be very easy to compensate.

See http://personal.ee.surrey.ac.uk/Personal/D.Jefferies/antennexarticles/cloops.htm
for info on calculating the radiation resistance. I believe that will
be helpful. I assume Reg's RJELoop1.exe uses essentially the formula
you'll find there. For your loop, that program says inductance is
2.69uH, conductor loss resistance is 46.2 milliohms, and radiation
resistance is 5.7 milliohms. Although the conductor loss resistance
(essentialy the same as you calculated above is "not bad," you need to

consider it with relation to the very low radiation resistance. A current in the loop will dissipate far more power in the resistive loss than in the radiation resistance. You ideally will keep the loss resistance small compared with the radiation resistance, though for receiving (because of the very high level of atmospheric noise on HF and lower frequencies) it matters not nearly so much as for transmitting. When transmitting, you want your power to go into radio waves, not heat. When receiving you only need signal greater than noise, and it is relatively easy to make an amplifier with low enough noise figure that even an inefficient antenna will result in an amplifier output whose noise is dominated by the atmospheric noise received by the antenna.

> It will be 0.02 Om

So 0.02 ohms sounds like a small amount, but it's almost half as much as the resistance of the copper loop. This may not be a bad thing, because the Q is so high that the bandwidth will only be about 3.5kHz assuming a lossless capacitor, and with the added loss the Q will be lowered to perhaps 1400, allowing a slightly wider bandwidth. With so narrow a bandwidth you need to be concerned about the stability of the varicap diodes' capacitance. Still, I would think a very high Q fixed capacitor supplying most of the total capacitance would be a good thing. Use only enough varicap to cover the tuning range you want. So for example, with 2.69uH inductance, if you want to cover 7.00MHz to 7.30MHz, you need 192.2pF at the low end and 176.7pF at the high end, a range of a little less than 16pF. You should be able to do that easily with two of your suggested varicap diodes, perhaps a couple of fixed 82pF high Q caps, and a high Q trimmer such as a piston trimmer to trim the center of the range.

It has more to do with the symmetry of the way the antenna is
mounted. You want to make sure that the capacitance to ground from
each side is as nearly the same as possible. You need to put the gap
in the loop (the feedpoint) either at the top or at the bottom of the
antenna, and for mounting it's often easier to put it at the top.
That way you can clamp onto the middle of the bottom of the loop to
mount to a pole... But if you have a balanced amplifier at the
bottom and bridge the gap symmetrically across the box that amplifier
is mounted in, it should also work well. I recommend to you the
discussion about small loop antennas in King, Mimno and Wing's
"Transmission Lines, Antennas and Waveguides."

I'm interesting in QRSS receiving. So narrow bandwidth is very useful
because it will help suppress noise from PC with I will connect to
radio.

Understand. Its uneasy to find high stable capacitor at this range.
But maybe I can find vacuum capacitors or something like this.

I think that gap at the bottom add more mechanical strength. And it
should be easy to connect coaxial cable.

> That way you can clamp onto the middle of the bottom of the loop to

30e RADIO FLEA MARKET in BEETSTERZWAAG on 31 May 2008

The radio flea market takes place to - 31 May 2008. Do you look for an exotic transistor kit or a super recipient, fixed and do manufacture kit...
or do meet of radio friends? Dan comes Saturday 31 May to the Friese radio market into Beetsterzwaag!

Many thousand visitors come each year from the entire Netherlands and Europe to this radio flea market spectacle, approx. 100 dealers, with most diverse articles, like transmitters, recievers, power supplies, antennas, software, hardware and literature.

Additionally of businessmen in the place also a flea market with many attraction organized for large and small. There are some sales desks free at the moment on the radio flea market, you can reserve by telephone & email, contact on to take with the executive committee. Down are these addresses.

How does one find after Beetsterzwaag? From direction Apeldoorn = > Zwolle = > Meppel = > Heerenveen = > Drachten, departure after Gorredijk Tijnje comes departure (28) Beetsterzwaag.

From direction Bremen = > Groningen = > Drachten = > Heerenveen, departure after Drachten Haven comes departure (28) Beetsterzwaag.

On 2mtr, 145,700 Digi Heerenveen can one to instruct leave themselves. Inlet is from 09:00 to 16:00 MESZ, into which Cafeteria one also boarded into this time.

This whole is organized of VERON FRIESE WOUDEN. Cordially Welcome in Friesland on the 30e FRM!

Look for more information at the site: www.frm.a63.org

Contact people, are:

I understand, but my point is that an antenna is reciprocal: there is the same percentage loss in the copper resistance whether receiving or transmitting.

...
>
> Is the BF981 will be good enough for this?

I would think almost any modern RF mosfet would be fine. You do not need very good noise figure for HF reception, even with an antenna with modest efficiency. Just make sure the amplifier input has high effective shunt resistance at the operating frequency-- greater than 200kohms--to preserve the high Q.
...
> Understand. Its uneasy to find high stable capacitor at this range.
> But maybe I can find vacuum capacitors or something like this.

It should not be that bad. C0G dielectric (also called NPO) capacitors have a _maximum_ temperature coefficient of 30ppm/C. The diameter of the loop itself, and therefore its inductance, will change with temperature in the same range, I believe. C0G capacitors, especially surface mount type, also have extremely low effective series resistance. I've found some C0G SMT caps that seem to have very close to zero temperature coefficient--it varies from lot to lot, apparently depending on the exact mix of the dielectric. What do you suppose the temperature coefficient of the capacitance of varactor diodes is? Note: 100ppm change in capacitance causes 50ppm change in resonant frequency. That's 350Hz at 7MHz. You probably wouldn't even notice that. It's only about 10 percent of the 3dB bandwidth of the antenna.

Cheers,
Tom

Not true. The voltage source also absorbs energy whenever
its voltage is positive but its current is negative.

I have no trouble with the concept, but the exposition you
have offered is weak.

Show me the reactance and its power function of time such that
it stores and releases the energy at the correct time.

Otherwise... Just handwaving.

> The reflected energy that is not dissipated in the source
> resistor at time 't' is stored in the reactance and dissipated
> 90 degrees later. Until you choose to account for that time
> delay, your energy equations are not going to balance.

I see no reactance that performs this function.

But the actual answer is that it is the voltage source which is
absorbing the energy for part of the cycle and delivering the extra
energy to the source resistor for the other part of the cycle.

So again, it is not the energy in the reflected wave that accounts
for the change of the dissipation in the source resistor.

> Are you going to try to tell us that the 18 watts from
> the signal generator are not dissipated in Rs???? If
> not in Rs, where????

As you note, the conditions at the original source have
not changed, so, since the energy in the reflected wave
was not dissipated in the source resistor in the original
circuit, it is not dissipated there in the revised circuit.

So, no changes at the original source.

Let us look at the circulator. Assuming a circulator
which does not accumulate energy, the net energy into
circulator must be zero.

0 = Pcp1(t) + Pcp2(t) + Pcp3(t)

Let us start with the 18 W producing 0 output.

Let us turn on the original source
Pg(t) = 50 + 50cos(2wt)

After one cycle, the wave reaches the circulator,
so at the circulator
Pcp1(t) = 0
Pcp2(t) = 50 + 50cos(2wt)
Pcp3(t) = -50 - 50cos(2wt)
which satisifies
0 = Pcp1(t) + Pcp2(t) + Pcp3(t)

Now turn on the right signal generator set to produce
18 W. Using the phase relationship needed to reproduce
the conditions from the original experiment
Pcp1(t) = 18 - 18cos(2wt)

This alters the voltage and current conditions at Port 2
of the circulator so that power delivered to this port is
now
Pcp2(t) = 32 + 68cos(wt)

and the power into Port 3 remains
Pcp3(t) = -50 - 50cos(2wt)

which still satisfies
0 = Pcp1(t) + Pcp2(t) + Pcp3(t)

Since turning on the 18 W generator altered the conditions
at Port 2, this change in line state propagates back towards
the original source and this state change reaches point Vg
Pg.before(t) = 50 + 50cos(2wt)
changes to
Pg(t) = 32 + 68cos(2wt)
which is good since this is the same power extracted from
the line at the circulator.

The changed load conditions at Vg alter the dissipation in
the source resistor as well as changing the power delivered
by the voltage source.

So where is the 18 Watts from the generator dissipated?
This is obvious. When the 18 W generator was turned on,
the power delivered to the circulator from the line (i.e.
the power delivered into Port 2, Pcp2(t) above) dropped,
but the power dissipated in the 50 ohm resistor stayed
the same. So it must be that the 18 W from Port 1 is now
being used to heat the resistor attached to Port 3.

Huh??? When the instantaneous source voltage is zero,
the instantaneous source power is zero. Yet, there
is instantaneous power dissipation in every resistive
element in a circuit with a reactive component. Where
do you reckon that power is coming from? It is apparent
that you are now just trying to pull my leg with your
ridiculous assertions. That's too bad. For awhile, I
thought you were serious.

I don't have time to teach you AC circuit theory which
you really do need to understand. The power function
for the reactance is of the same form as it is for a
resistance, i.e. V(t)*I(t). I haven't seen you include
that reactance power function anywhere. When you do,
you will find your "missing" power and balance your
energy equations.

Please go take an AC circuits course. That's exactly
what a reactance does. The source terminals see +j44.1
ohms of reactance looking into the transmission line.

The average of a sine wave is 0. Positive half the time,
negative half the time, sums to 0.

Perhaps you are confusing average with root-mean-square?

This is the third opportunity you have had to clearly
identify the component and show that its energy flow
as a function of time is exactly that needed to store
and release the energy in the reflected wave.

Since you have not done so, I conclude that you can't
find it either.

So true.

> is instantaneous power dissipation in every resistive
> element in a circuit with a reactive component. Where
> do you reckon that power is coming from?

Fairly obviously, the equations I have presented show
that it comes from energy stored in the line.

Recall that
Pg(t) = 32 + 68cos(2wt)

For some of the cycle, energy flow is from the line
towards the resistor and the voltage source.

But this is not the energy in the reflected wave
which has the function
Pr.g(t) = -18 + cos(2wt)
and only flows in one direction, towards the source.
And it is this supposed energy that can not be
accounted for in the dissipation of the source
resistor.

You need to read more carefully. I made no statement about
the energy incident upon port 2, only about the energy
flowing into port 2, which, after the 18 W generator is
turned on, is
Pcp2(t) = 32 + 68cos(wt)

Yes indeed. The reactance looking into the line. But
the reflected wave is not going into the line so this
is not a reactance that it sees.

Recall, the whole premise of forward and reverse waves
is that they see the line characteristic impedance, in
these examples, a real 50 ohms with no reactance.

Keith Dysart wrote:
> Yes indeed. The reactance looking into the line. But
> the reflected wave is not going into the line so this
> is not a reactance that it sees.

Part of the reflected wave energy is going into the
reactance along with part of the forward wave energy
when the instantaneous interference between those two
waves is destructive at the source resistor. Anything
else would violate the conservation of energy principle.
That same energy is returned to the source resistor 90
degrees later as constructive interference. Your missing
energy is in the reactance. Now you know why Hecht said
instantaneous power is "of limited utility". Where the
instantaneous energy is at any point in time is a
complicated mess that you haven't solved.

It is the average power that really matters and all the
average reflected power is dissipated in the source
resistor when the reflected wave is 90 degrees out of
phase with the forward wave but under no other conditions.

Instantaneous power is completely irrelevant to the
average power data posted on my web page. You are
saying that because my pickup has black tires, it
is not a white pickup. My article stands as written
with a disclaimer about any importance being attached
to instantaneous power.

Walter Maxwell didn't deal with instantaneous powers.
Steven Best didn't deal with instantaneous powers.
To the best of my knowledge, the instantaneous power
straw man was invented by you for the purpose of
muddying the waters.

Your instantaneous power analysis is also incorrect
because you completely ignored the instantaneous
power in the system reactance. You have completely
ignored the role of destructive and constructive
interference. You cannot possibly understand where
the energy goes until you understand interference.

We have reached the end of the discussion road and
hashed it to death. If we are still in disagreement,
we are just going to have to agree to disagree.

If we have two pipes each carrying one gallon of water
per minute in opposite directions, we can agree that
the net flow of water is zero. But you are taking it
one step farther and arguing there is no water flowing
at all which is a ridiculous assertion. I'm going to
ignore this latest obvious diversion.

Of course we have a "right". And I've gotten my answer. Asking for a test protocol for your antenna tests is too much to ask. Okay. So I'll sit back and patiently watch for any results proffered.

But you might want to think about it. What if some parameter in the test process is such that will make the antenna test out as performing poorly when in fact it does not.

I think you have now chosen the correct path because a lot of people
are going to have to eat crow.
I am not sure if you are computor savvy but it appears that those who
do
are holding back on sharing the tipped radiator thing.
Can you do it for those who are not computor savvy because at the

moment nobody has stepped forward
and helped them determine if it is correct or not. At the moment
Richard has stated it is a myth
but he is not computor savvy so his remark is off the cuff. So again
amateurs are being left in
the dark by the computor savvy people of this newsgroup who refuse to
help.
What gives?
regards
Art

Hi Richard,

A scaled model of an antenna the size of two shoe boxes? Gives new meaning to the toys kids used to collect called "matchboxes."

If going from 160M to half a meter was achievable, then going to a couple of centimeters should be a walk in the park. If scaling down 300 times was achievable and saw great boon, then scaling down another tenth must bring even more efficiency gains.

Why was this option left on the table when it results in a vastly simpler construction and a superior product?

Something tells me NO ONE knows why.

That's more easily said than done. One of the critical characteristics of a small antenna is loss. And to correctly replicate loss in a scaled antenna requires scaling the conductivity of the conductors as the square root of the frequency. To scale to a higher frequency requires that the conductivity be better than the original. Unless the original is made from lead and the scale factor moderate, this wouldn't be possible.

Roy Lewallen, W7EL

Yes, that should be fine. I suppose a transformer will be a
convenient way to better match the FET amplifier output to a
transmission line. The transformer can be physically quite small.
MiniCircuits and some others (CoilCraft; M/A-Com; ...) sell
appropriate transformers, and of course they are easy to make if you
have an appropriate core. Also you can feed power to the amplifier
through the transmission line. The transformer secondary can return
to a bypass capacitor instead of directly to ground, and your DC feed
appears across that capacitor. The circuit I used for 150kHz loops
used a shunt voltage regulator in the amplifier, and by feeding the
other end with a controlled variable current, I could avoid problems
with uncertain voltage drop in the line plus connectors, and also use
the current through the regulator to control the tuning voltage on the
varicap diodes. So everything was done through the transmission line.

Cheers,
Tom

If there were two transmission lines, then I could see
why you might want two pipes in an analogy.

But since there is only one transmission line, an
analogy with one pipe makes more sense.

So you want to argue that when there is one pipe
with no water flowing, what is really happening is
that one gallon per minute is simultaneously flowing
in each direction. In the same pipe. At the same
time. I don't buy it.

You should think a bit more about
Pcp2(t) = 32 + 68cos(wt)

It is the time rate of energy flow into the port.
It can trivially be computed from the voltage and
current functions at that port.

It sums with the energy flows into the other ports
appropriately to satisfy the principle of conservation
of energy.

All is well.

And there is only one pipe for each port.

It is unnecessary. But if you believe me wrong, show me
where it goes, compute the values, and show how it
accounts for the energy that is not dissipated in the
source resistor.

Averaging is a mathetical operation applied to a function.
In this case a function of time.

The underlying function of time conveys more information than
does just the average which is why just dealing with averages
can lead one astray.

> Instantaneous power is completely irrelevant to the
> average power data posted on my web page.

Well, it does disprove some of your claims so I can see
why you like to belittle it.

I mean that I will use you suggestion about balanced amplifier. I'll
use two FETs. I'll place one more tube from middle of the loop to the
gap. And I will use this point as ground point for balanced amplifier.
In this case I will have differential signal at FET Drains and I will
need transformer for put this signal to coaxial cable.

The transformer can be physically quite small.

My cable only 10m long. So I this it would be unnecessary. And I will
operate with three signals:
1. Varicaps voltages.
2,3 - voltages at secondary FETs gates.

Unfortunately for your argument, molecular water and
EM waves are considerably different animals. Water
energy traveling in opposite directions in a pipe
interact. EM waves traveling in opposite directions
in a transmission line interact only at an impedance
discontinuity or at an impedor. As long as only a
constant Z0 environment exists, the forward wave and
reflected wave pass like ships in the night. For you
to prove otherwise, you are going to have to define
the position and momentum of a single photon. Good
luck on that one.

It is unnecessary to account for all of the instantaneous power???? Your problem is greater than just a simple misunderstanding of the laws of physics by which we must all abide.

The DC energy is stored in your vehicle's battery until it is needed to start your vehicle. That delay between stored energy and needed energy is related to the (undefined) wavelength. Think about it.

In an AC circuit, the reactance has no say as to when to store the energy and when it is delivered back to the system. It is also related to wavelength which is defined.

When the source voltage is zero at its zero crossing point/time, the instantaneous power dissipation in the source resistor is NOT zero! Doesn't that give you pause to wonder where the instantaneous power is coming from when the instantaneous power delivered by the source is zero???? Why do you ignore that power and try to sweep it under the rug?

You are making the mistakes that your EE 201 professor warned you not to make. You are superposing powers, something that all the gurus on this newsgroup will condemn. Until you learn not to superpose powers, you will remain forever ignorant. Richard C. made the same mistake when he declared that the reflections from non-reflective thin-film coatings on glass are "brighter than the surface of the sun". If one ignores the laws of physics, anything is possible.

There is a condition where it is valid to superpose powers. That is when (V1^2 + V2^2) = (V1 + V2)^2
You have obviously not satisfied that condition and are paying for your violations of those laws of physics.

Until you give up on your superposition of powers, I
cannot help you.

Show the expressions and the numbers for how many angles
can dance on the head of a pin???? Shirley, you jest.
This is not the proper venue to try to establish your
new religion.

> Are you really going to let me be the last man standing
> this time?

No, you died in action a few weeks ago and don't realize
it. It happened the first time you superposed powers when
(V1^2 + V2^2) is not equal to (V1 + V2)^2. Too bad you
are incapable of comprehending exactly what that means.
You can easily work it out for yourself but you haven't
yet attempted to do so. Hopefully, one of the resident
gurus whom you trust will explain it to you.

Until you correct your ignorance on that subject, *you* are
just handwaving. I suggest you contact someone who is more
knowledgeable than you on the subject. Ask Richard C. to
prove his assertion that the reflections from a non-reflective
thin-film surface are brighter than the sun. If you detect
what is wrong with his argument, you will know what is wrong
with yours.

I doubt that, Richard. When the length of a dipole is
much, much greater than the diameter of the wire, the
antenna will scale appropriately. But what happens when
the length of the antenna is not a lot greater than the
diameter of the wire?

It is the same problem as trying to use water in scale
models of boats. It just doesn't work.

Yes...very good. That should help keep the loop nicely balanced,
especially if you build it all very symmetrical. That one more tube
can also then help support the loop mechanically. Good luck with your
project!

Previously explained, as you may have forgotten, with
the energy cyclically returned from the line.

For your convenience, I copy from a previous post:

Recall that
Pg(t) = 32 + 68cos(2wt)

For some of the cycle, energy flow is from the line
towards the resistor and the voltage source.

But this is not the energy in the reflected wave
which has the function

Pr.g(t) = -18 + cos(2wt)
and only flows in one direction, towards the source.
And it is this supposed energy that can not be
accounted for in the dissipation of the source
resistor.

And, as expected
Ps(t) = Prs(t) + Pg(t)

Energy is conserved.

Cecil Moore wrote:
"When the length of a dipole is much, much greater than the diameter of the wire, the antenna will scale appropriately.

Yes. An assumption made to ease calculations is that the diameter of the radiator is vanishingly thin. Art`s antenna configuration is something of a mystery to me but I infer that it may be a dipole in which the two lengths of wire have been wound into coils and not extended to their maximum length. Further, my guess is that the dipole is resonant so that it readily accepts energy. Such antenna elements, I believe usually emit energy in the radial mode and resemble the continuously loaded vertical antenna as shown on page 6-28 in the 20th edition of the ARRL Antenna Book.

Description of the resonant element includes:
"The relationship between length of wire needed for resonance and a full quarter wave at the desired frequency depends on several factors. Some of these are wire size, diameter of the turns, and dielectric properties of the form material to name a few. Experience has indicated that a section of wire approximately one half wavelength long, wound on an insulating form with a linear pitch (equal spacing between turns) will come close to yielding a resonant quarter wavelength. Bill Orr says about the same thing on page 78 of "Vertical Antennas". Continuing from the Antenna Book: "Therefore, an antenna for use on 160 meters would require approximately 260 feet of wire spirally wound on the support."

If Art has made a dipole of two such 1/4-wave elements, it should have about a full wavelength of wire which I believe is consistent with his miserly description.

Performance of a full wave of coiled wire will be much less than the performance of the same wire stretched out into a straight line at the same height above earth.

Best regards, Richard Harrison, KB5WZI

Cross-posted to: rec.radio.amateur.antenna,sci.electronics.design,sci.electronics.basics

Hi All,

I always hear that antennas have to be matched to their radio, but in receivers (such as FM and shortwave radios) I see mostly long random length antennas used, and these antennas -- be they a telescoping whip or a long wire out a window -- are used over some really wide bandwidths. How is this possible if an impedance match must always be maintained for radios? And since there cannot be a good match over such wide bandwidths with any (typical) wire antenna, what is the downside to using these completely unmatched long antennas for receivers? (Poor gain patterns with lots of nulls? Lower sensitivity due to bad noise figure or gain match for any LNA or frontend amp? Degraded overall antenna gain)?

Thanks; I'm very confused on this subject!

Bill,
That's one of those "sort of" kind of questions. It depends a lot on the particular receiver and what frequency range you plan to listen to, and then on the amount of space you have for an antenna.
In general, receivers that listen to the lower frequency bands, HF for example, are more sensitive than those that are used for the higher bands (VHF, UHF, SHF). That means that to hear a typical signal a specifically designed antenna having the exact output impedance as the receiver's input impedance isn't required. Almost anything will work to some extent. The receiver just isn't that 'picky', since it typically has more 'hearing' ability than required.
There's a 'catch' though. Reducing the amount of signal losses in that 'whatever' antenna is going to make the resulting signal getting to the receiver that much stronger. Something always nice to have, but there are practical limits. If that 'whatever' antenna meets your requirements, then it's as 'good' as anything, sort of. If it doesn't, then making that antenna less 'lossy' is also nice. That "less 'lossy'" thingy also includes making it directional, longer, shorter, higher, whatever, to increase the amount of signal getting to the receiver. So, looking at it from that point of view, the antenna ought'a be reasonably 'close' to what will typically 'work' well on the received frequency. Huge range in that 'close' quality and the definition of what 'works' means.
There is no 'perfect', 'do everything', antenna. Just too many factors involved. 'Higher' and 'longer' tends to 'work' better than 'lower' and 'shorter', in general. Which, like any generalization, is never always true.
That's the sort of 'long', half-assed, technical answer. The 'quick-n-dirty' answer is, no, they don't have to be 'matched' to the receiver. Which says nothing about transmitters.

The difference between antennas used for receive only and antennas used for send/receive is that in the former case you are not going to fry the radio's insides because of the mismatch.

But I'll bet that as you change the settings on your antenna tuner you hear the received signal go up and down-- in particular, reception goes up as you get a better match.

Correct. Those are downsides. The upside is convenience and simplicity.
It's sub-optimal; but it works!

The best transfer of energy is achieved when the antenna impedance matches
the input circuit impedance of the receiver.
This should be the case for the entire band of the desired received signal.
It is not always feasible to do this and it is often not necessary. Today's
receivers have very high gain and excellent selectivity.
They need very small signal strengths to operate and excess signal is
attenuated.
So a piece of wire used as an antenna in an area where the signal strength
is large will not do any worse than a perfectly matched antenna.
In an area where the signal strength is weak (like Mars) matching of the
antenna to the front end of the receiver is desired.
There are other considerations for transmitters.

Tom

The AGC circuit in receivers has enough dynamic
range to compensate for low amplitude signals
from a mismatched HF antenna. The S/N ratio
on HF is mostly external to the receiver.

Dear Bill (no call sign):
It depends. The goal of a receiver is to have a satisfactory
signal-to-noise & distortion ratio. Many factors enter into that ratio.

Let us consider just the antenna: Below something like 30 MHz, it is
easy to have receivers that are quiet relative to noise picked up by most
antennas. In other words, below something like 30 MHz, the SNR is
determined outside of the receiver and tweaking the tuning between the
antenna and receiver just increases or decreases the volume. At VHF and
higher frequencies, the noisiness of the receiver tends to be a significant
player. It has long been known (see MIT Radiation Lab volume 18) that the
maximum SNR occurs close to a conjugate match between the antenna and
receiver's first stage.

However, many consumer VHF-UHF receivers (FM broadcast, TV, scanners)
are presented with such large signals that there is little point in tweaking
the interface between antenna and receiver for an even larger SNR.

In the early days of radio astronomy, when we were still using vacuum
tubes, a lot of attention was paid to having the right amount of mis-match
so as to maximize SNR.

So: HF and below: be concerned about the directivity of the antenna
(is it reasonably sensitive in the direction of interest).
VHF and above: have the antenna's impedance, transmission line's
impedance, and receiver's input impedance be within a factor of 2 of each
other AND point the antenna in a desired direction.

Regards, Mac N8TT

Considering that it meets Maxwells requirements and is at least a
wavelenght
of a radiator my expectations are much higher than yours
I suspect that the output will exceed that of a 160 M antenna which
has a ground plane.
I also suspect that if I diddn't concentrated so much on small
physical size it could easily be uprated
to compete with a yagi!
I would anticipate that in a couple of years the top band will have

twice as many users that it has now.
I am hoping also that its small size will allow for receiving
abililities in line with the angle of incoming
radiation via its manouvarability. Of course if all is already known
about radio this would seem impossible
but in a few weeks I myself will have a few QSOs to see how it matches
up to my expectations.
The archives show all the building instruction but it appears that
readers have concentrated on
nonsensical retorts without reading the content. If an antenna is at
least off one wavelength
and is in equilibrium I see no reason why it should not beat existing
antennas with ground plane losses
regardless of its shape or size. Time will tell. Either way the
experimental trail undertaken I have found to
be very rewarding as many other amateurs have had when experimenting
with antennas and who refuse
to accept that all is known

More correctly, it's _easier_ to make an HF receiver with a good noise figure, and harder to do so as the frequency goes up.

However, atmospheric noise goes _down_ as the frequency goes up. So for weak-signal work a receiver designer has a lot of motivation to make really quiet front ends on VHF and higher equipment. Basically if the radio is cheap (i.e. if it's for consumer use) then the front end may as well be made of wood. If the radio is used for long-distance communication (i.e. microwave links, space communication, some military or amateur radio) then designers will go to great lengths to get the noise figure down.

In areas where it matters receive antennas are matched, and are something other than random wire. This is why you can go to Radio Shack and buy TV antennas* -- they're designed** to be both directional and a good match over the broad frequency ranges of TV signals.

Get into amateur radio or military communications and you'll find many different permutations of directional, matched antennas on receive.

Note: For many LNA designs, the best signal/noise ratio occurs at an impedance that is close to, but not really, a perfect conjugate match. The signal is coupled to the amplifier best at the conjugate match impedance, but sometimes the noise is enhanced even more.

* or could -- does Rat Shack still carry antennas?
** kinda -- they're really designed to _look_ like they'd make a good antenna, but they're better than rabbit ears.

I have on order a tilting system for my antenna to probe the
polarisation of incoming signals
for maximum audio clarity and gain.
There are instruments out there that can automatically tell you the
polarisation
without one taking the trouble to pan the antenna in different
directions.
Anybody out there follow such a procedure with the antenna or use a
homebrew
or commercial instrument to save time?
Regards
Art

That brings up an intersting question I never did get a good answer
to...

It is my assertion that an LNA that is physically at room temperature
(290K) can have a noise figure no better than 3 dB (i.e. its effective
noise temperature is 290K) IF it is also conjugatly matched i.e.
looks like 50 Ohms.

Yes you can make the noise figure better than 3 dB, but then you must
either cool the device or MISMATCH it to the line.

In other words if it looks like 50 Ohms and it is physically at 290 K,
it's effective noise temperature must also be 290K.

How could it be otherwise?

Comments plese.

Mark

of course all is known, we have been trying to tell YOU that but you won't believe it and insist on trying things that are known NOT to work. you will learn, it will be a long and hard experience from what we have heard from you on here, but you will learn someday that there ain't no such thing as a free lunch when it comes to antennas.

OH NO! now you have done it! i hope cecil doesn't see this or you have just
openend another endless energy sloshing around thread! what does happen if
the antenna isn't matched to the radio? where does the mismatch energy
go???

Nothing free....I have done a lot of work. Now I get the benefits of
that work.
I disagree that all experiments on antennas should stop based on the
proweress of your particular brain. You have consistently over
estimate
your abilities

>has a ground plane.

Hi ï¿½ther,

Suspect away, but the best you could accomplish is in the digits to
the right of the decimal place of percent efficiency. On the S-Meter
scale of any listener, that would be an invisible shift of the needle.
Of course, their only experience of this antenna will be at least a
10dB drop from a conventional antenna which would be easily seen on
the S-Meter.

>I also suspect that if I diddn't concentrated so much on small
>physical size it could easily be uprated
>to compete with a yagi!

Suspect some more, but that is not going to happen unless you have
more elements, widely dispersed (and we've been there before, and the
yagi is more efficient than any of your usual suspects). As you
discard planarity, so do you discard directivity unless you drive
every element directly. You don't do this, and you have yet to
exhibit the knowledge of why you have to, to meet your claims.

This lack of knowledge, in itself, clearly reveals that not all is
known about antennas. However, others who can accomplish recovering
this directionality do exhibit this knowledge. The readers can
discern how the remainder of your post lacks in this regard.

>I would anticipate that in a couple of years the top band will have
>twice as many users that it has now.

The Solar cycle will have more to say about that than any suspicion.

>I am hoping also that its small size will allow for receiving
>abililities in line with the angle of incoming
>radiation via its manouvarability.

No need for hope, transistor pocket radios have been doing that for,
what, 50 years? Even there, loop sticks have probably been around
longer than that. Try transmitting through one and discover fire
again.

>Of course if all is already known
>about radio this would seem impossible

No, if everything written above has been forgotten (or never learned,
same thing) THEN it would seem impossible.

>but in a few weeks I myself will have a few QSOs to see how it matches
>up to my expectations.

Without comparisons, any contact is bound to raise the estimation of
such expectations.

>The archives show all the building instruction but it appears that
>readers have concentrated on
> nonsensical retorts without reading the content.

The same archives show a multiplicity of "instructions." However, as
they all suffer in comparison to simple antennas, they are easily
dismissed against the claims presented for them.

It merely takes diligence to take them on one at a time, as they are
announced, and line them up like dominoes to watch them tumble in
line. The archive contains these results for all time. This design
is no different in that respect than the last, or the several before
the last.

>If an antenna is at
>least off one wavelength
>and is in equilibrium I see no reason why it should not beat existing
>antennas with ground plane losses
>regardless of its shape or size.

And yet they don't, and so reason is not a principal component here so
much as wish and hope braced with the courage of ignoring knowledge.

>Time will tell. Either way the
>experimental trail undertaken I have found to
>be very rewarding as many other amateurs have had when experimenting
>with antennas and who refuse
>to accept that all is known

The sad truth is that only one, maybe two here have the professional
contacts to antenna test sites, and you have refused their offers.

I have dog-eared the post:

It is notable you always fail to identify "Him." Throughout the entire post you use the impersonal "He" and never a name.

So, I am going to turn you slowly on the spit over the fire of dignity, are you going to use "His" name? We have call signs that makes us brothers, can Cain acknowledge Abel?

Hi Bill,

It is not always needed if the signal is strong enough. If the signal
is not strong enough, then you can obtain considerable gain through
tuning.

Tuning also brings other advantages by rejecting signals that could
depress your radio's sensitivity.

wrote:

>This is why you can go to Radio Shack and buy TV
>antennas* -- they're designed** to be both directional and a good match
>over the broad frequency ranges of TV signals.

I once cranked out an NEC2 model of a Radio Shock TV antenna to see
what it really did over the 54-890MHz range. It was fairly horrible.
There were actually a few frequencies where the impedance was close to
300 ohms. There were also a few frequencies where it actually had
some gain. At some frequenies, it had more gain in the reverse
direction than forward. As an example of a "directional and a good
match" antenna, that typical Radio Shock TV antenna doth truly suck.

I'll see if I can find the model. Unfortunately, it may have been on
a hard disk that crashed a few years ago.

Not having a good match between the antenna and LNA has several
effects. The mismatch will affect the system noise figure thus
reducing sensitivity. Some LNA's are not unconditionally stable and
will oscillate when presented with a weird source impedance. At HF
frequencies, the atmospheric noise level is above the receiver input
noise level, so considerable mismatching can be tolerated. About
about 20MHz, this is no longer the case, and a match is required.

Antennas are also affected by their load impedance. A highly
directional yagi antenna pattern can easily be ruined by mismatched
coax or LNA input impedance. For the antenna to work as advertised,
it has to see the rated load.

I bought this old-fashioned style radio from LL Bean to listen to a
Prairie Home Companion on.

http://www.llbean.com/webapp/wcs/stores/servlet/CategoryDisplay?page=crosley-radio&categor
yId=56013&storeId=1&catalogId=1&langId=-1&parentCategory=7985&cat4=7984&shop_method=pp&fea
t=7985-tn

It is broadcast locally on PBS radio, but I am in an apartment and am
not getting strong reception. Beyond moving the radio (which I have
tried to several locations) is there anything else I can do to improve
it?

Thanks, Scott

> has a ground plane.

How many people do you know that use elevated ground planes
on 160m? This may or may not be a trick question.

> I also suspect that if I diddn't concentrated so much on small
> physical size it could easily be uprated
> to compete with a yagi!

I suspect it would also be capable of browning the food, if
said food was placed close to the device when high power
was applied.
But the last time I checked, food warmers are not known
as very good radiators of RF.

> I would anticipate that in a couple of years the top band will have
> twice as many users that it has now.

Because all of a sudden you show up using a sub par antenna?
How would this effect the number of users of that band?
Why would anyone modify their operating habits because
you refuse to use an antenna that is halfway efficient?

> I am hoping also that its small size will allow for receiving
> abililities in line with the angle of incoming
> radiation via its manouvarability. Of course if all is already known

I have no time to waste on sub par antenna designs.

>If an antenna is at
> least off one wavelength
> and is in equilibrium I see no reason why it should not beat existing
> antennas with ground plane losses

How many people do you know that use elevated ground planes
on 160m? This may or may not be a trick question.
But even if one was to use an elevated ground plane, or
even a ground mounted vertical, who are you to say if
the system is lossy or not?
I know of plenty of vertical systems on 160m which will
whip your puny shoe box antenna like a long lost stepchild,

regardless of the level of equilibrium noted.
Whatever that means...

> regardless of its shape or size.

Regardless of shape or size... yea right...

>Time will tell. Either way the
> experimental trail undertaken I have found to
> be very rewarding as many other amateurs have had when experimenting

The only thing I "know" for sure is you have your
head stuck so far up your whiny kazoo it has clouded all rational
thought.

As an example..

>I disagree that all experiments on antennas should stop based on the
>proweress of your particular brain. You have consistently over
>estimate your abilities

#1, define proweress...
#2 define your abilities, and then we will all vote as to who
has the greater level of proweress between the particular
brains in question.

Everyone is brain dead, except for prior Art. lol...
BTW, I said I would wait for your grand test before
I commented further, but seeing as you continue to spew
your silly bafflegab, and also horses ass comments to anyone
that dare question your silly crap, I retire my earlier stance.
MK

Andy writes:

As a practical matter, if the background noise heard in the receiver
increases when the antenna is attached, the antenna is good enough.

This means that the atmospheric noise, in the frequency range that
the receiver is tuned to, is greater than the internal receiver
noise....

It also means that any signal that is to be received that exceeds
the
atmospheric noise, will be heard......

Unless you are using some signal processing that can detect signals
below the atmospheric noise level, this is a very good rule of
thumb....

Consider an airborne LORAN antenna, used on aircraft, to receive
100 khz signals. It works out that around 22 inches is the length
where
the atmospheric noise exceeds the general receiver noise for most
receivers. Making the antenna longer will pick up more desired
signal,
but also more atmospheric noise, in the same ratio.....so the SNR
doesn't
get much better. Note that a matched antenna for 100khz will be
many many hundreds of feet long.... but is never used either in boats
or airplanes, since a "matched" antenna serves no advantage to
sensitivity (SNR)....

These are rules of thumb, and useful approximations, but, in
effect,
you don't need a great antenna unless you are trying to receive a weak
signal....or have a method to increase the SNR by signal processing.

If what I suspect is true, would not the coax also need to be scaled?

Ha ha Richard, I assume you are aware that this is a joke given that a helical antenna is circularly polarized. I am not so sure about this "You" character though, he seems to take it seriously. And Art...well, the British have been known for their dry humour too. Good one, Art.

For a receive antenna, you don't need to worry as nearly as much about an impedance match as you do with a transmitter. You are dealing with much higher gain on the input side as you are on the output side.

>the gaps to 3 inch's rather than keep them to the original Cobwebb spec?

Changing the end spacing in this sort of antenna alters the
capacitance between the ends. This has a very significant effect on
the impedance at the feedpoint, and thus on the SWR. If the original
design had a different spacing and had a good SWR match, and you
change the spacing to 3" and don't make any compensating change to the
wire length, I suspect that you'll find that the antenna is no longer
as well matched and won't work as well with a 50-ohm feed source.

If the changes in tip spacing / capacitance aren't too serious, you
could probably compensate with an antenna tuner/transmatch. There
would be some amount of excess loss in the feedline due to the higher
SWR, but it might not be enough to affect performance significantly.

On the other hand, if the CobWebb with the 3" spacing has had its
radiator lengths adjusted to compensate for the change in tip-to-tip
capacitance, it might match up just fine. If that's the case, then
I'd expect that its performance would probably be indistinguishable
from an equally-well-matched Cobbweb with different tip spacings.

When I built a 2-meter halo antenna, I found that a change of 1/16" in
the tip spacing made a big difference in the SWR. After several
attempts to construct a tip spacer that was neither too wide nor too
narrow (but was *just* right, like a good bowl of porridge) I gave up.
I just used one of the "too wide" spacers, and then added a bit of
aluminum tape at the end of one tip and trimmed it until the SWR was
as good-as-it-got.

That beer in your hand was also cooled in a 300K ambient. How is that
possible? (Hint: the fluctuation-dissipation theorem only applies to
systems in thermodynamic equilibrium. The moment you turn on the power,
that assumption is violated, just as it is in your domestic refrigerator.)

An ordinary room-temperature diode has a noise temperature of 150K
(Tambient/2) as you can show in about 3 lines of algebra, starting from
the diode equation and the shot noise and Johnson noise formulas.

Perhaps, Owen. My view is that the radiation from a helical antenna (Art's design) is circularly polarized, that is to say that the electromagnetic field rotates about the axis of the helix in the direction of the helix turn. What is your understanding? If in fact it happens to be the same as mine, then please tell me how Art could possibly "pan the antenna in different directions" for "maximum clarity and audio gain" (as you could with linear polarization)?

I look forward to learning about your alternative concept of circular polarization, and, how maximized clarity and audio gain could be achieved using Art's stated methods. Thanks,

Well, I 'm not an expert, but it seems that with a transmitting antenna, the idea is to transfer as much power as possible to increase efficiency, and so the antenna needs to be closely matched to the output of the transmitter for best results. But the receiving antenna is a different problem, since no power from the antenna is needed to drive the receiver, and so who cares about the match? The idea with the receiving antenna is to get the most voltage and highest S/N ratio with no load. The input to the receiver should be buffered with a high impedance FET amplifier, or some such, so the receiver draws almost no power from the antenna. This leaves you free to design the antenna and input tuning circuit for the highest Q and lowest noise figure without worrying about impedance match.

Just my opinion.

Are you talking about the possibility of Art communicating with other people who are transmitting on similar helical circularly polarized antennas where CW vs CCW direction must be considered? I dismissed this possibility entirely. Most hams's signals arrive either veritcal, norizontal or somewhere in between (not rotating) originating at a linear polarized source. Is he communicating with satellites? I really haven't heard of helix antennas on the HF bands other than the Unwin compact model. If so, then yes, you can only switch the feedpoint to change from CW to CCW and that can make a BIG difference in gain. The probability of Art finding another HF helical to QSO with should be negligible to null. Satellites are another matter.

If this is his compact wonder, it is probably not an axial mode helical.
(I don't know that one could ever describe an axial mode helical as
'compact'.)

Normal mode helicals deliver linear polarisation.

Sure, try extending that length of antenna and see what happens. If
it helps, then you have a chance of finding the optimum length for
your particular situation. Quit when you don't hear any more
improvement (or when you run out of wire or places to run it).

OK mike one last time.
Make a former to wind apon.
Set it up vertically and secure so that it doesn't fall over.
Get two reels of insulated wire preferbly pre wound paired
wire on each reel. Join the paired wires
Put the joint at the rear of the former with one reel to the left
and one reel to the right.
Wnd one wire clockwise and then wind counterclockwise the
wire from the other reel. Repeat these two functions making
sure the overlapped wires stay parallel with each other.
When you have completed the length of the spool then join
one wire to another wire from the opposite reel. You now have two
wires in your hands
one from each of the reels. These two wires are what you connect to
the transmission line..
Suggestions for the former. Make two cross arrangements using 1/2 inch

plastic piping.
At each of the 8 ends place a tee connection. Four pipes around a foot long can the join the two sections,
Use tees instead of elbows so the antenna is easier to mount.
If you want it to be all frequencie:
Cut a 1/2 inch plastic pipe in half,' length wise.
Make wire loops and fit them over the cut pipe and solder them tight.
Place a quick start threaded rod inside the cut pipe with a motor at one end.
Make a electrical wiper to place on the quick start thread to make electrical
connection to the loops as the motor turns.
Connect a meter to one of the start wires and disconnect it from the joint.
Place a sowing needle on the other end of the instrument and pierce the
wires in sequence until one
gets to the coax connection points marking each wire that is connected to the meter.
Connect the marked wires to the loop that were made sp electrical contact
can be made to the threaded shaft
Connect the shaft to one of the wires that consists of the feed points.
Rejoin the wire connections at the start point so that now you have a complete electrical
circuit starting at the feed points
Place assembly anywhere and apply power and have a qso.
Now will somebody that is savvy with computors do that excercise that I suggested
with regard to tipped radiators and report on it before you make this antenna or start
tilting towers around ten degrees sinc the change is not worth it when calculating total gain?

> is supplying zero watts at that time but Prs(t) = 100w.
> Where is the 100 watts coming from?

Vs(t) = 1.414cos(wt)

After settling, from some circuit analysis...

Vg(t) = 100 cos(wt+45degrees)
Ig(t) = 2 cos(wt-45degrees)

Vrs(t) = Vs(t) - Vg(t)
= 100 cos(wt-45degrees)
Irs(t) = Ig(t)
= 2 cos(wt-45degrees)

Is(t) = Ig(t)
= 2 cos(wt-45degrees)

Ps(t) = Vs(t) * Is(t)
= 100 + 141.4213562 cos(2wt-45degrees)

Prs(t) = Vrs(t) * Irs(t)
= 100 + 100 cos(2wt-90degrees)

Pg(t) = Vg(t) * Ig(t)
= 0 + 100 cos(2wt)

For confirmation of conservation of energy, the above
is in agreement with
Ps(t) = Prs(t) + Pg(t)

Ps(t) = 100 + 141.4213562 cos(2wt-45degrees)
so, Ps(t) = 0, occurs whenever
141.4213562 cos(2wt-45degrees)
is equal to
-100
which, for example, would happen when 2wt = 180 degrees
or wt = 90 degrees.

At this time, again for example, the energy being
dissipated in the source resistor
Prs(t) = 100 + 100 cos(2wt-90degrees)
= 100 + 0
= 100

Since no energy is being delivered from the source,
(Ps(t) is 0), then given
Ps(t) = Prs(t) + Pg(t)
the energy must be coming from the line. Let us
check the energy flow at the point Vg at this
time
Pg(t) = 0 + 100 cos(2wt)
= -100
as required.

So the energy being dissipated in the source
resistor at this time is being returned from
the line.

Just for completeness we can compute the line
state at the point Vg in terms of forward and
reverse waves...

Vf.g(t) = 70.71067812 cos(wt)
Vr.g(t) = 70.71067812 cos(wt+90degrees)
Vg(t) = Vf.g(t) + Vr.g(t)
= 100 cos(wt+45degrees)

If.g(t) = 1.414213562 cos(wt)
Ir.g(t) = 1.414213562 cos(wt-90degrees)
Ig(t) = If.g(t) + Ir.g(t)
= 2 cos(wt-45degrees)

Pf.g(t) = Vf.g(t) * If.g(t)
= 50 + 50 cos(2wt)

Pr.g(t) = Vr.g(t) * Ir.g(t)
= -50 + 50 cos(2wt)

And since
Pg(t) = Pf.g(t) + Pr.g(t)

= 0 + 100 cos(2wt)
confirming the previously computed values.

It is valuable to examine Pr.g(t) at the time when
Ps(t) is zero. Substituting wt = 90degrees
into Pr.g(t)...

Pr.g(t) = -50 + 50 cos(2wt)
= -50 -50
= -100
which would appear to be the 100 watts needed to
heat the source resistor. This is misleading.
When all the values of t are examined it will be
seen that only the sum of Pf.g(t) and Pr.g(t),
that is, Pg(t), provides the energy not provided
from the source that heats the source resistor.
wt=90 is a special case in that Pf.g(t) is 0 at
this particular time.

The line input impedance does have a reactive
component and it is this reactive component that
can store and return energy. The energy flow
into and out of this impedance (pure reactance
for the example under consideration) is described
by Pg(t).

In summary,
Ps(t) = Prs(t) + Pg(t)

and by substitution, if the solution is preferred
in terms of Pf and Pr,
Ps(t) = Prs(t) + Pf.g(t) + Pr.g(t)

Ps and Pr alone are insufficient to explain the
heating of the source resistor.

Agreed. However, the short 18" antenna is commonly used for handheld
and aircraft Loran receivers. However marine Loran antennas are
typically 8ft long.
<http://shakespeare-marine.com/antennas.asp?antenna=5220>

That's not the only reason that Loran antennas are rather short. If
the antenna were longer, the impedance would increase, causing it to
pickup more percipitation static, atmospheric noise, and 60Hz
harmonics. A longer antenna would also not be as narrow band and low
impedance as a short (loaded) antenna. The relatively narrow
bandwidth is helpful for eliminating broadcast, beacon band, and other
forms of interference.

Incidentally, that's also one reason why some remote Loran systems
have a pre-amp that really burns some watts. It needs to handle the
out of band overload and stay linear. If the antenna were made
longer, the amplifier would need to handle proportionately more power
(and probably melt). Some details in the patent at:
<http://www.google.com/patents?id=ONUrAAAAEBAJ&dq=4875019>
The "background" section is worth reading. The other reason for the
amplifier is to give the antenna system a 50 ohm output impedance so
that cheap coax can be used.

Yes. Such antennas include small diameter coils making up solenoids. The turns act as small stacked loops.

A small loop acts as a short dipole but with its E and H fields interchanged. See page 58 of the 3rd edition of "Antennas" by Kraus, Marthefka, et al.

I did not say that. The quote is from somewhere else.
I am sure that he will be happy about the facts that you
have revealed to him as a personal favor and a book
that he can read up for himself what "Normal mode" means
Then explain it to you so you understand what you read
In the mean time I will try loading up a solenoid on 20 M
to see how many people are using them..

Art wrote:
"I have an on order a tilting system for my antenna to probe the polarisation of incoming signals for maximum audio clarity and gain."

That may be interesting but do you ever recall cross polarization of an incoming ionosphere reflected signal being unreadable because polarization was wrong?

So many different and quickly changing path variations exist in the ionosphere that the best antenna to use is based on probability.

E.A. Laporte says on page 215 of "Radio Antenna Engineering":

"To make best use of this effect (randomness of ionospheric waves) it is desirable to employ complimentary antennas for transmitting and receiving."

Most commercial HF circuits I`ve experienced and seen use horizontal polarization. It is because much severe man made interference arriving at a receiving antenna is vertically polarized.

I apologize to Art Unwin. It was Owen Duffy who wrote:
"Normal mode helicals are commonly used on HF."

A normal mode helical antenna radiates perpendicularly to the axis of the helix. The axial mode helix antenna invented by John Kraus radiates in the direction of the axis of the helix.

Richard,

Mr. Un win has not sufficiently described his antenna for anyone to determine how much/if any radiation is axial or normal. We do not know the relationship between coil diameter, length and wavelength. I thought this was all a joke because I had assumed axial mode. It is possible to understand Art's concerns seriously if you assume normal mode. But normal mode is not the function of a true helical mode antenna, it is merely using a coil as an 'antenna shortener' by adding distributed inductance, like a strectched out slinky....there are many HF CB antennas constructed that way thru their entire length and they do likely have normal polarization. It is up to Art to answer to us how his secret design is working, normal or axial mode? Art, what is your coil ID, antenna length and frequency of operation? If it turns out you are axial, then you know what to do: be able to switch the feed point. If it is normal, then I suggest you consider a modified inverted V antenna construction, if possible, at 45 degrees, as having a higher probability of closer polarization match than straight horizontal or vertical, just as is the case with a normal dipole.

Hi Owen

I have no disagreement with your thoughts. I do want to point out that
the short helical antenna named Quad Helix does give good CP normal to the
helix axis.

Bill;

I haven't looked at the back of a radio in a long time, but those that I
have looked at usually had a trimmer capacitor that helped tune the
antenna to the radio input. This is the impedance match you are looking at.

If you can run a wire to a water pipe or electrical ground and over to
'close proximity' to your radio, it will probably increase reception.
It did for my little transistor radio when I was a kid (a few years back).

Hi Uncle

If you are ambitious, you could consider building a multiturn loop antenna
(http://www.mindspring.com/~loop_antenna/)and coupling it to your receiver
by wrapping several turns of wire around it. A 2 foot diameter loop can
improve reception appreciably, when tuned properly.

Perhaps you're repeating the attempts of those experimenters of long
ago, who knew and discarded.

Which, contrary to your previous assertions, agrees with what I have said previously. This is the destructive interference energy stored in the feedline 90 degrees earlier and being returned as constructive interference to the source resistor. It's impossible to sweep it under the rug when the source power is zero, huh?

All power comes from the source. Since power is being delivered to the source resistor at a time when the source is delivering zero power, it must have been previously been stored in the reactance of the transmission line.

> the helix axis.

Hi Jerry,

John Kraus' explanation of "normal mode" is where the radiation normal to the helix axis dominates. On that basis, the Quad Helix (which he discusses in his book) is neither an axial mode helix nor a normal mode helix, it is large enough that it has significant radiation both normal and axial, but not large enough to be dominated by the axial lobe, and it is a multi-filar helix which allows CP normal to the helix axis.

The Quadrifilar Helix is an interesting antenna, and I was aware of your particular interest from previous reading.

I don't know of a mono-filar normal mode helix that gives CP, but I expect that two of them with phased feeds could be used in the same way as crossed dipoles.

We are of course all guessing what Art had in mind, there is a conspicous and familiar lack of coherent detail.

I make amplifiers with 50 Ohms input impedance and 300pV/rtHz input-
referred noise. By your assertion, that should have been impossible.
The trick is that the input impedance obtained by feedback: The
cooled resistor trick. It works.

The intriguing question is:
1. Do you just stop reading as soon as you find a snippet
that aligns with your claim?
2. Do you keep reading, but do not understand because you
are so gleeful at finding a snippet that aligns with
your claim?
3. Or do you read, understand, but choose to disingenuously
ignore that which follows the snippet that aligns with
your claim?

Regardless, if you use the snippet above to support
your claim, you have effectively modified your claim.
You are now saying that the reflected energy is
dissipated in the source resistor only at particular
times, such as when the source voltage is 0, and that
you are not interested in what happens during the rest
of the cycle.

For example, if you were to do the same analysis,
except do it for t such that wt equals 100 degrees,
instead of 90, you would find that you need more terms
than just Pr.g to make the energy flows balance.

When wt equals 100 degrees
Ps = -28.170
Prs = 65.798
Pg = -93.96
so, as expected
Ps = Prs + Pg

And
Pr.g = -96.985
Pf.g = 3.015
Ooooppppss, no way to make those add to 65.798.

But
Ps = Prs + Pf.g + Pr.g
since
Pg = Pf.g + Pr.g

So all is well with world.

> All power comes from the source. Since power is
> being delivered to the source resistor at a time
> when the source is delivering zero power, it must
> have been previously been stored in the reactance
> of the transmission line.

This is true. But it is, of course, Pg(t) that
describes the energy flow in and out of the line,
not Pr.g(t).

So are you now agreeing that it is not the energy
in the reflected wave that accounts for the
difference in the heating of the source resistor
but, rather, the energy stored and returned from
the line, i.e. Pg(t)?

Note also, that when wt is 100 degrees, not only is
the source resistor being heated by energy being
returned from the line, the source is also absorbing
some of the energy being returned from the line
(Ps = -28.170).

Hi Owen

Art who??

Again, I am in full agreement with you on the limited application of nthe
term "Normal" to the radiation of a helix. In addition, I suspect there is
little need to elaborate, but, if a person had need, he could make a
bi-directional CP radiator from 1/2 of a Quad helix.

Keith Dysart wrote:
> Regardless, if you use the snippet above to support
> your claim, you have effectively modified your claim.

False. My claim is what it has always been which is:
An amateur radio antenna system obeys the conservation
of energy principle and abides by the principles of
superposition (including interference) and the wave
reflection model. Everything I have claimed falls out
from those principles.

Your claims, however, are in direct violation of the
principles of superposition and of the wave reflection
model, e.g. waves smart enough to decide to be reflected
when the physical reflection coefficient is 0.0. Your
claims even violate the principles of AC circuit theory,
e.g. a reactance doesn't store energy and deliver it back
to the system at a later time in the same cycle.

> You are now saying that the reflected energy is
> dissipated in the source resistor only at particular
> times, such as when the source voltage is 0, and that
> you are not interested in what happens during the rest
> of the cycle.

You haven't read my article yet, have you? Here's a quote:
"For this *special case*, it is obvious that the reflected energy
from the load is flowing through the source resistor, RS, and
is being dissipated there. But remember, we chose a special
case (resistive RL and 1/8 wavelength feedline) in order to
make that statement true and it is *usually not true* in the
general case."

If there is one case where your assertion is wrong, then
your assertion is false. I found that special case when
the source voltage is zero that makes your assertions
false.

> For example, if you were to do the same analysis,
> except do it for t such that wt equals 100 degrees,
> instead of 90, you would find that you need more terms
> than just Pr.g to make the energy flows balance.

Yes, you have realized that destructive and constructive
interference energy must be accounted for to balance the
energy equations. I have been telling you that for weeks.

I repeat: The *only time* that reflected energy is 100%
dissipated in the source resistor is when the two component
voltages satisfy the condition: (V1^2 + V2^2) = (V1 + V2)^2.
None of your examples have satisfied that necessary condition.
All it takes is one case to prove the following assertion false:

"Reflected energy is *always* re-reflected from the
source and redistributed back toward the load."

You appear to think that if you can find many cases where
an assertion is true, then you can simply ignore the cases
where it is not true. I have presented some special cases
where it is not true. It may be true for 99.9% of cases,
but that nagging 0.1% makes the statement false overall.

Equally false is the assertion: "Reflected energy is
always dissipated in the source resistor." The amount
of reflected energy dissipated in the source resistor
can vary from 0% to 100% depending upon network
conditions. That statement has been in my article from
the beginning.

> So are you now agreeing that it is not the energy
> in the reflected wave that accounts for the
> difference in the heating of the source resistor
> but, rather, the energy stored and returned from
> the line, i.e. Pg(t)?

I have already presented a case where there is *zero*
power dissipated in the source resistor in the presence
of reflected energy so your statement is obviously just
false innuendo, something I have come to expect from
you when you lose an argument.

There's lots of ways to do this. calibration is always an issue.

For instance, two helices wound with opposite senses can be run through
a variable combiner. (the helices can be on the same form, and are
coincident.

There'a variety of tripole antennas used for this sort of thing, too.

3 crossed short, resistively loaded dipoles or loops is also used.

A very clever scheme uses half loops sticking out of a conductive sphere
as a simultaneous E and H field probe. The electronics is all inside
the sphere, and you bring the data out on fiber optics.

Or, use diversity combining. Several researchers in France have done
work with this, and discovered there's very little correlation between
the ordinary and extraordinary rays, so diversity combining is extremely
effective on HF skywave paths. They used physically co-located antennas
that had different polarization sensitivities (a loop and a whip, as I
recall).

Interference polarization is not necessarily the case. (I believe
there are measurements that show it is essentially random). More what
it is has to do with the antenna pattern of horizontal and vertical
antennas for sources at ground level and reasonably close. For example,
A horizontal antenna not too high over a ground plane has a null right
at zero elevation.

Yes. If anything there's been a bit of a rebirth in antenna sales as people start hearing about free over-the-air (ATSC) HDTV.

(Speaking of HDTV... Fry's is advertisiting ATSC->NTSC converters for $59, coming very close to the $49 I was predicting a while or so ago... Joerg will be pleased. :-))

This implies only that the antenna/receiver *matching* is good enough... yes?

(I'm thinking that you would still sometimes prefer a highly directional
antenna over just a dipole even though both increase the background noise.
I.e., in both cases the antenna matching is good enough, but without the
directionality the antenna itself might not be good enough to eliminate
interference, overloading, etc. from sources other than the one you're
interested in.)

Jim'
My 160M antenna is totaly at 70 feet. Not below or above. With the
tilting and pan mechanism and a couple of relays
it is possible to automate it so that every so often it will cycle
thru all modes using the single antenna. When a louder signal arises
then it is simple to stay on that polarisation
. This combiation thus is a reduction of land space required for two
or more separate antennas.
I was just curious as to what other hams were doing and it appears to
be nothing in this area.

Hi Jim,

As Richard pointed out, a goniometer (what, a 100 years old already?)
works fine for this. I bought one at a Ham swap when I was a
teenager. I also pointed this goniometer/antenna application out to
Arthur to demonstrate what he thought was novel was quite old (in
reference to the work of Tosi and Bellini). Arthur does not
acknowledge prior inventors, so this topic consistently re-emerges
with a fair periodicity. It should reappear around July again.

For those who want to see a schematic of the goniometer and antenna
application, here is a perfectly good example:
http://www.elektronikschule.de/~krausg/Longwave/Collection/Receiver_Techniques/On%20the%20art%20of%20NDB%20DXing/chapter5/On%20The%20Art%20of%20NDB%20DXing%20-%205.htm

A potential problem with a goniometers is that they aren't particularly broadband, although, I suppose that if the relative coupling ratios change with frequency, at least they're consistent.

The example cited below is an example of this. You adjust for best null/peak on your desired signal, which is narrow band. The setting for one frequency isn't likely to be the same as the setting for another frequency.

In an application where you want to combine multiple skywave paths, one probably wants something that can be automatically adjusted.

Lots of hams have done things with polarization diversity combining for HF. Check out Ralph, W0RPK's site at:
http://showcase.netins.net/web/wallio/POLAR.html

He has some actual recorded levels over a 20-30 second interval on a 10m skywave signal.

The problem with physically moving the antenna is that you need a fairly fast positioner, since the fades (in any one polarization) are on the order of 1 second. With a single antenna, you also don't know, a priori, which way to move it or when to move it (is that an overall fade, or is the polarization changing). You can use a scanning or dithering technique (much like conical scan for high gain parabolas), as long as the scan period is much less than the fading time scale.

With two co-located antennas, you've got lots more possibilities, and with modern signal processing hardware, it's cheap.

(and, of course, most FM car radios use some form of diversity combining these days, as do virtually all Wireless LAN access points)

Jim, Allow mw to share my thoughts with you on my antenna design
and where my experimental trail is leading. I say experimental
because the trail cannot be pursued in the mind only unless one is
absolutely sure one knows everything
and thus cannot be faultedn
I constantly experiment to prove that my mind is correct or corrected
if experimentation proves it to be in error which thus require re
evalution
and redirection. without experimentaion you have nothing but a talking
head sitting on a couch.
My antenna is actually several antennas rolled up into one. As a
contra wound helix on top of each other we have a ambidextrious
antenna
that with tilting provides horizontal and vertical polarisation
because the windings and counter windings cancel each other out.
If one circular sign al is dominant I expected the cancellation
remainder will be added to the horizontal and vertical polarisation
signal.
At the same time eithe of the cancelled polarities can be issollated
from all otheres by shorting it out.
I also wanted purity of polarisation to which I have referred to in
the past where signals are not at 90 degrees to earth but tipped 10
degrees plus. Hopefully this will all work out as I have solve the
combination polarisation problem while keeping the readiator small
enough for three degree movement. I have to do all this to first
confirm that the direction that I am taking so I can move on to arrays
using tilted radiators
fashhioned in a a array in equilibrium where two degrees of freedom
with respect to volume which is forcasted by the combination of Gauss
with Maxwell. Obviously every structure has to have the ability of
many experiments as possible to flush out any errors in my analysis as
possible in the early stages. Fortunately my single radiator pursuit
with respect to size came out o.k. and thus with the incoming
mechanism for tilt and scan operation can now procede without the huge
mechanical difficulties imposed by planar and large radiators. This
comming portion of the experimental trail is of utmost im portance to
ensure that the comming arrays are truly in equilibrium such that the
spacings of

the individual small radiators can be reduceded over those of planar arrays. In my work with the small signal radiator I have found it possible to make them directive such that it may well render the idea of small arrays as moot when considering the advances made by zeroing on the signal polarity and pursuing a delay phase addition circuit with what I have at present. A long trail that was started years ago which I find very rewarding where I can now see the light at the end of the tunnel.
Best regards
Art Unwin KB9MZ.....XG (uk)

Hi Jim,

That would be called a telephone.

The objection to adjustments being necessary is duly noted; the same
characterisitic is one that has been historically prized within the
Ham world.

My goniometer was untuned.

That gets my vote. I had a clock radio that had about a foot of wire hanging out the back. I extended the wire to about 3ft with it running up the corner of the room on the wall. Reception was much improved. Imagine what a really good antenna would do.

Jim Lux wrote:
"Interference polarization is not necessarily the case. --------For example, A horizontal antenna not too high over a ground plane has a null right at zero elevation."

Good point. The worst noise is likely local and arrives via ground wave. Ground waves are vertically polarized because horizontal components of an electric field are exactly canceled at the surface of a perfect reflector.

Examination of the radiation patterns of horizontal antennas confirms that they invariably have zero response at zero elevation on their best azimuths.

From researching susceptibility of antennas to noise I came across a statement interesting to me in Terman`s 1955 opus on page 929:

"----a loop antenna responds much less to the electric induction field than does a simple wire antenna of comparable intercept area. This is of importance because electric induction fields predominate in the man-made noise that causes disturbances in radio receivers, and this explains in part the popularity of loop antennas in broadcast receivers."

Thanks Dave for all the info. I will give it ago with the original spacing.
I have also ordered the MFJ-259B to help tune it. Just have to work out how
to use it properly. Hi.

Most Iv'e seen are basically just coils and not designed to be narrow band. My comment was more that the transfer function varies not only as a function of the moving coil position, but also frequency. I suppose one could build a tuned one.

If this were true then most television broadcast stations would have nearly zero field strength near the earth over much of their present coverage areas.

Instead, the fields there are directly related to the peak ERP of the TV station -- which typically is radiated in, or a few tenths of a degree below the horizontal plane.

Richard Fry in a private e-mail noted that I had misquoted E. A. Laport
who wrote:
"---it is desirable to employ complementary antennas for transmitting
and receiving."

I typed "complimentary" which means praise or a gift. Surely Laport
meant antennas which work together to perfection which is even better
than getting them free. I made a typo.

I apologize for my mistake.

Tony,
This may have already been suggested as I only got about half way through the replies. As a test, isolate the receiver from _everything_ (ground & ac power) except for a 12 volt battery and the loop. I did this in order to receive 600 meter test transmissions. It turned out that most of my noise was related to underground supplied AC power. I can now easily copy several of the WD2XSH test transmissions with a 5 foot square indoor loop with no preamp.
Note that I am not transmitting, and I am only suggesting this as a test to verify that your AC power line isn't the problem.

Regards,

bob baldwin

I'll have to ponder his statement, but my reg flag is waving...
This almost seems akin to the shielded loop controversy.
It may well be true in whatever manner he is considering, but
for some reason it doesn't seem quite right to me.
Maybe I'm missing something, so I'll await further comments.
MK

This is another lie that Art fabricated for rhetorical reasons. Nothing new.
Nobody is saying that. For TV, broadcast gain is absolutely a dependency on
ERP within a few degrees offset from the horizontal plane.

Has anyone used their products ?

I looked on E-ham net reviews, and the results
are a mixed bag.

What i'm interested in is their new "Frontier"
multi-band antenna (consisting of a remote screwdriver
HF antenna, and a UHF/VHF antenna that are mounted
on a tripod).

But for $675, the price is in "outrageous"
territory.

Wondering if anyone has actually purchased/used
one, and if it's worth the money.

Yeah, i'm lazy, don't feel like messing around with
manually moving taps on a coil, or have to adjust
lengths of the antenna sections each time i switch
bands.

2nd Question: ..... mounting a scanner antenna
near the antennas for the rig, what do most folks
use to prevent blowing out the rx front end on
the scanner ? (from keying up the HF rig).

Over the air HDTV is superior to cable and satellite HDTV. They may sell more outdoor antennas as soon as it becomes clear that, from the 1996 telecommunications, not only did the FCC ruling on small satellite dishes overrule the homeowner association covents restricting dsmall satellite antennas, they ALSO overruled covenants restricting outdoor TV (i.e.yagi type) antennas...this was done to promote fair competition for cable, satellite and broadcast TV. I did put up a regular radio shack yagi style outdoor TV antenna back then and the HOA did contact their lawyer and found they could do nothing about it. If I ever splurge and buy my 1080p, I will do it again because the OTA picture is absolutely the best.

Ah, when popularity displaces correctness!

But, I can see the confusion when you place a mandrel into a drill to
wind the coil.

Or should it be a persondrel? Is PC still in vogue?

Owen

PS: my (rather old) Concise Oxford Dictionary thinks a mandrill is a
"Large fierce West African baboon", fierce I guess when bound with wire.
It hasn't caught up with the alternative use for mandrel, well not by
1979.

Hi Roy

I'm curious to know why you didnt use stainless steel as an example rather
than lead as your example.

I can`t find it now, but I believe Mark, NM5K on this thread wrote that my quotation from page 929 of Terman`s 1955 opus raised flags. I said I was surprised in my original posting. I was aware at the time that Kraus shows identical field paterns for a small loop an a short dipole, but the E and H fields are exchaged between the two antenna types. The Kraus diagrams are on page 58 of the 3rd edition of "Antennas".

I`ve learned not to quarrel with Terman. So, I reread the page 929 quotation. I posted it correctly. He did say a loop antenna responds much less to the electric induction field than does a simple wire antenna of comparable intercept area.

So I looked for a similar statement in Terman`s "Radio Engineering" in an edition published in 1947. On page 664, I find:
"In the case of a doublet antenna, the electrostatic induction field becomes proportionally stronger than the magnetic induction field as one comes closer to the antenna. With the loop antenna the reverse is true."

We know that the induction, or near, field is equal to the radiation field at about 1/6 wavelength. Closer to the radiator, the induction field is much stronger. Farther away, the radiation field predominates Our intrest is usually in the radiation, or far field. Measurements are usually made several wavelengths away from an antenna to be sure the induction field has become insignificant.

I`ve thought how and why my experience confirms Terman`s statements but I won`t bore anyone with these thoughts.

Best regards, Richard Harrison, KB5WZI

Note that his analysis proves that destructive interference
energy is indeed stored in the reactance of the network and
dissipated later in the cycle as constructive interference
in the source resistor at a time when the instantaneous
source power equals zero.

Like so many bons mots lifted from Terman, we have to use a bit of care in extending it to everyday amateur applications.

A very small loop responds less strongly to the electric field than a very small dipole only within a fraction of a wavelength of the antenna. Beyond that, it actually responds more strongly to the electric field than the dipole does. So at HF, for example, it would be helpful only in rejecting electric field noise being radiated within a few feet of the antenna.

I suspect that the antenna is a tuned circuit on top of coax, and it
needs that coax to radiate effectively. So just scaling the antenna
wouldn't translate to the same results?

Nice. Too bad it only goes from about 400-800MHz, which covers the
UHF channels. It doesn't work for the VHF channels. Looking at the
4NEC2 plots, it's not very good on VSWR, has reasonable gain, but only
on the lower UHF channels (no problem because the higher channels are
being auctioned off by the FCC).
<http://www.qsl.net/va3rr/hdtv/hoverman.htm>

>A home brewed double Gray-Hoverman. Apparently, they work pretty well

>panties in a bunch.

The local OTA digital TV is on Channel 8 (KSBW) at roughly 87MHz. The
reflector of a suitable Gray-Hoverman antenna should be about 1.5
meters wide. I think the aesthetics committee will be banging on the
front door rather quickly. What's that giant fly swatter doing on the
roof? I wonder if a TV antenna can legitimize a solar cell array if
the array is mounted on the TV antenna?

"Comparing some commercially available antennas"
<http://www.hdtvprimer.com/ANTENNAS/comparing.html>
I really like the negative gain (i.e. loss) in some of the commercial
VHF antennas. Too bad they didn't run antenna patterns, as many such
TV yagis have more gain in the reverse direction, than forward.

Incidentally, I once built a vertically polarized omnidirectional OTA TV antenna intended as a disguise antenna (if you consider a 2.5 meter white fiberglass pipe to be suitable disguise). It worked well enough from about Channel 8 to about Channel 47. Not much gain (about 4dbi) but the big problem was that it was prone to receiving ghosts (reflections). I should probably resurrect the design, rename it "Ultimate Digital Disguise Magic Super-Antenna", and join the hype instead of fighting it.

The main reason is that many years ago I was involved in using physical models scaled up in size in order to optimize microstrip transitions and other features used for time domain equipment having rise times on the order of 10 ps. At that time, I looked to see if it was possible to model the loss accurately, and found I'd need a semiconductor to do it. I recall that lead was about the least conductive common metal available. So I tossed that one out in my example.

I don't remember investigating stainless or other steels, but that might indeed be a way to do it. To make a strictly accurate scale model, the permeability and permittivity (dielectric constant) stay fixed with frequency, so a non-magnetic stainless steel would be necessary. However, since the skin depth is inversely proportional to the square root of permeability, a magnetic material has the loss of a non-magnetic material having a conductivity lower by a factor equal to its relative permeability. So a magnetic material such as steel or magnetic stainless steel might be used to extend the range of possible loss values available for making larger physical models. There's a very large number of steel and stainless steel alloys, and good information on the required parameters can be hard or impossible to find. So samples would probably have to be measured.

In the case in question, however, a smaller scale model was proposed, and we can probably assume that the original is made from copper. So it's not really possible to create a smaller scale model which

accurately imitates the loss of the original.

Yes. If the coax is radiating, it's part of the antenna. To make an accurate scale model of the antenna, you have to scale the entire antenna (that is, every radiating conductor), not just some part of it which someone has declared to be "The Antenna". In this case, however, radiating coax isn't likely to be a major fraction of the total loss, so scaling it in a model probably wouldn't make much difference to the loss. Its diameter might have a noticeable effect on how much current it gets and therefore how much it radiates, though, which is an argument in favor of scaling it.

Ghosts are a big problem where I live. Or multipath and the resulting
dropouts the case of DTV broadcasts. That's why I like highly
directional designs (both horizontally as well as vertically). Other
than that, I can get all of our local stations with rabbit ears and a
UHF loop.

All of our DTV stations broadcast on UHF as the VHF band in the Seattle
area is pretty much filled up with the legacy analog stuff. I'm not
certain what the stations plan on doing once the digital cut over is
complete. They might move their digital signal down onto their analog
slot or abandon the analog slot altogether. That will be a factor in
what kind of antenna I put up.

Since I don't own one, you have to take this as a generalization.

Any HF mobile antenna is going to be a compromise, just won't be as 'good' as a real-live full sized antenna. If that same mobile HF antenna is used as a base, it's still gonna be a compromise. Of course, if you don't have the room for that real-live full sized antenna, then that little one is certainly a better option than no antenna at all.

The cost of this antenna relates more to convenience than anything else. Just how much is convenience worth to you? Being naturally cheap, I can change a lot of 'taps' for that amount of money, so I'm not likely to own one very soon (after I win the lottery!). I don't have any deed restrictions, and quite frankly, I couldn't care less what the neighbors think about antennas... within reason.

The VHF antenna and the HF antenna. As previously said, distance between the two makes for 'better'. What's the 'best' distance? A nice answer is, as much as possible. That's the same for any two (or more) antennas not just HF/VHF. Along with not having a 'zap' happen, it's also nice if the radiation/reception patterns are disturbed as little as possible.

Great answer, huh? Lot's of specifics, CYAs, and so on. Oh well...

I have seen this expressed as a sensitivity to E and H that imply an impedance that varies with distance from the antenna, and that it "bounces around" (that is a technical term, you know) eventually converging on 120*pi.

Is that correct?

> Beyond that, it actually responds more strongly to the electric field

> in

Roy, accepting that the response of the loop and dipole to electric and magnetic fields are different close the the antenna, do they not eventually converge on sensitivity to E and H in the ratio of 120*pi when immersed in the far radiation field?

I don't know if I have put that sensibly.

My understanding was that when placed a very long way from the sources, neither one had any advantage in response to the desired signal just by virtue of their type (loop vs dipole).

They do converge, but only after one change in slope. More below.

Yes.

That's correct.

E/H is the impedance of the field and, close to a small loop, the impedance is small as expected. (As a receiving antenna, this means that it's relatively more sensitive to the H field than the E field if the source is very close.) However, the impedance rises rapidly as you get farther from the loop, and at a fraction of a wavelength, it actually overshoots 276 ohms. Then, after reaching its peak, it monotonically approaches 276 ohms from the high side as you get farther and farther away. A short dipole acts just the same, but with E and H reversed: the impedance is high very close to the antenna, then overshoots on the low side, and from there approaches 276 ohms at a great distance. So at all

points except very close, the impedance of the loop's field is actually higher than that of the dipole's. In practice, the difference is negligible except perhaps for a very small region, so they behave virtually the same for signals coming from any distance of, say, a wavelength or further away.

You can very easily see this behavior with NEC-2 or EZNEC modeling, using the near field analysis. The free demo version of EZNEC is adequate.

And the best thing is that there's no size limit in the OTARD rules for
these antennas. the 1 meter limit is ONLY for satellite antennas. OTA
terrestrial has no size limit. Build that 20 bay curtain array.

The OTARD rules say, "tough beans" to the HOA. No size limit.

I wonder if a TV antenna can legitimize a solar cell array if
> the array is mounted on the TV antenna?

There are other laws in many states that prohibit a HOA from restricting
alternative energy sources (like solar panels for hot water or
electricity, wind generators)

From: richardharrison@webtv.net
Message-ID: <24886-47E0358E-918@storefull-3257.bay.webtv.net>
Source record: 26998

Examination of the radiation patterns of horizontal HF antennas (Dipoles, horizontal rhombics, etc.) near the earth confirms that they invariably have zero response at zero elevation on their best azimuths. (Should have made it clear that the antennas were near the earth, not just their patterns.)

The earth reflects energy which strikes it at a grazing incidence inverting the phase on reflection. The incident and reflected HF horizontally polarized waves add to zero producing a null along the earth`s surface.

I did not include enough detail in my earlier posting so Richard Fry replied:
"If this were true (zero response at zero elevation on their best azimuths) then most television stations would have zero field strength near the earth over much of their present coverage areas."

If TV station antennas were 1/2-wavelength or less above the earth, their field strengths near the earth would truly be near zero over much of their present coverage areas, VHF, or UHF.

Best regards, Richard Harrison, KB5WZI

There's no explicit size limit stated for the antennas. However, it
could be argued that building an antenna which is larger than
necessary for good reception is not protected... prohibited
restrictions include those which "preclude(s) a person from receiving
or transmitting an acceptable quality signal from an antenna covered
under the rule."

Hence, if you can receive an acceptable-quality signal on all channels
with a 1-bay antenna, the FCC *might* consider as reasonable a
restriction against putting up a 20-bay antenna.

The rules also say "Masts higher than 12 feet above the roofline may
be subject to local permitting" and that the rules do not preempt
"legitimate safety restrictions".

It's clear that a blanket "no on-the-roof TV antennas" restriction by
HOR rules or CCRs is generally unenforceable.

what i have seen is a 'coil form' is something that remains inside the coil
once it is complete. a 'coil former' is a removable frame or device that
you wind the coil on and then remove. These can be for large coils that are
then supported by something else, like tank coils in amps. Or for coils
that are then put on a core that is built separately, as in a high voltage
power transformer.

And the FCC has carefully stayed away from defining "acceptable" . In fact, in one case, they've said that it's in the judgement of the person receiving the signal (The HOA wanted to make the homeowner put the antenna inside the attic, claiming that since they were close to the transmitter site, that an acceptable signal was available). (I can't find the reference off hand.. it's in Maryland or Virginia, as I recall)

One might also want to look up the very interesting case of Stanley and Vera Holliday (5 masts, 30 ft high, 3 dishes, etc.)
http://www.fcc.gov/Bureaus/Cable/Orders/1999/da992132.txt

I spent a while trying to hunt down what "acceptable" might be in FCC rules terms (e.g. what's a minimum performance standard for a Cable TV).. It's pretty tough to find a numerical standard. There are standard service contours which relate to RF field strength, but they're also statistical.

For digital receivers, in fact, on 21 Jan 2001, the FCC: "Denied requests to set performance standards for digital receivers, expressing

concern that the effect of setting such standards at this point would be to stifle innovation and limit performance to current capabilities. The Commission said it would continue to monitor receiver issues;" As recently as June, 2007, an article in CED Magazine said:"The FCC has never before adopted receiver performance specifications or interference rejection requirements. It has the authority to do since Senator Goldwater introduced a bill that became Public Law 97-259 in 1982, which added the italicized language below to the Communications Act:..."

ATSC has a document A/74 which defines a recommended practice for receiver performance, but it's kind of a clunky document, based on technology that was available in 2003-2004, and not really intended for this sort of thing. FWIW, the FCC assumes you need 7dB SNR for UHF and 10dB for VHF, with an assumed 7dB NF.

So, one could claim you need that 20x20 bay antenna to get enough signal to compensate for your horrid transmission line and terrible receiver.

>
> The rules also say "Masts higher than 12 feet above the roofline may
> be subject to local permitting" and that the rules do not preempt
> "legitimate safety restrictions".
The FCC has set a pretty high bar on safety restrictions. They have to be clearly articulated and justified in the rules (i.e. no "in the opinion of the architectural review board, that's unsafe"). The 12 foot thing is a building code issue. The city or jurisdiction would have to have a fairly specifically articulated justification.

>
> It's clear that a blanket "no on-the-roof TV antennas" restriction by

>

Yep.. In fact, can't even have a "must put antenna in position X" or "must plant or paint" rule, unless the cost of compliance is trivially small (as in <$5, see the Meade,KS case) and has ZERO effect on reception

>than that, I can get all of our local stations with rabbit ears and a
>UHF loop.

I live too far away from the local digital TV xmitters to get reliable
reception. My rule of thumb is that if OTA analog TV reception is
marginal, digital TV will be worse.

Highly directional antennas are the right way to eliminate ghosts
(reflections). However, I keep running into problems with f/b (front
to back) ratio problems, where the ghosts are reflected from behind
the antenna. That's where the lower gain, but higher f/b ratio
antennas, such as a barbeque grill backed bowtie array, makes more
sense. My preference is to use single channel narrowband yagi's for
maximum gain, but that gets really ugly as one per channel is
required.

>All of our DTV stations broadcast on UHF as the VHF band in the Seattle
>area is pretty much filled up with the legacy analog stuff.

We have Channel's digital 10 (KSBW) and digital Channel 12 (KNTV)
<http://en.wikipedia.org/wiki/KNTV>
<http://en.wikipedia.org/wiki/KSBW>

I once did a paper design for a trapped yagi, designed solely for channels 8 and 11 (the analog channels) and no others. It probably would work, but nobody was interested in buying one.

>I'm not
>certain what the stations plan on doing once the digital cut over is
>complete.

All of them. The station owners would need to be insane not do do digital. It's a free extra channel with the oportunity to sell additional services (i.e. data broadcasting).

>They might move their digital signal down onto their analog
>slot or abandon the analog slot altogether. That will be a factor in
>what kind of antenna I put up.

Duh... I never thought to ask the local broadcast engineers what the channel lineup is going to be after the Feb 17, 2009 fire drill. I'll ask.

Every day, I go on an extended exercise constitutional. One day, I decided to count outdoor TV antennas in my mountain neighborhood. My guess is that I passed about 100 houses and only saw three outdoor antennas (which looked ancient and inoperative). I'm wondering if anyone watches OTA TV in my area.

3379. "Splitter" Losses

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-18 23:32:15 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <w4OdnfY4qYVmzX3anZ2dnUVZ_v2pnZ2d@comcast.com>
Source record: 26851

Hello,

Expect to purchase an A/B switch box to switch the coax lead from a single receive-only antenna to one of two scanners.

Got to wonder about using a "Splitter" instead.

What is the typical insertion loss for a Splitter ?
(the Scanner freq's go up close to 1 GHz)

I will always be using, and have On, only one of the receivers at a time.
Thus the other spigot will be always be looking at a receiver that is Off.

Will I still have the insertion loss if only one receiver is on (but the other receiver that is Off would still be connected to the Splitter) ?

Thanks,
Bob

A decent splitter, driven by a source whose impedance is the impedance
the splitter is designed for, delivers half the available power to a
matched load on either side, independent of what's hooked to the other
side. A decent splitter should not have more than a dB or so internal
loss. That said, antennas and receiver inputs are seldom very close
to their nominal impedance, so YMMV. In general, though, don't expect
one receiver being on or off to matter significantly to the other
receiver.

Cheers,
Tom
who recently designed, built and installed a 1-to-8 splitter plus
amplifier here at work for a receiver antenna system. The one here
really is good about isolation among the outputs; shorts or opens on
one output affect any of the others by a couple tenths of a dB max.

The State of Schwarzenegger has had a "Solar Right Act" since 1978.
See:
<http://www.sandiego.edu/epic/publications/documents/070123_RightsActPaperFINAL.pdf>
The Calif Civil Code Section 714 limits the power of HOA's and
governments to restrict solar installations.
<http://www.akeena.net/cm/About_Solar_Power/California_Civil_Code_714.html>

The problem is that term there seems to be some variations in what
constitutes "reasonable restrictions" which are allowed by the law. If
the purpose of the CC&R's is to maintain some semblance of aesthetic
integrity, the local courts have ruled it "reasonable" for them to
block the installation of just about anything with a visual impact.
The interpretation of "reasonable" varies in different jurisdictions
but locally, it seems almost random.

Incidentally, I've read CC&R's that were apparently written perhaps 50
years ago. They're full of restrictions based on race, color,
ethnicity, and such, which are obviously unenforceable. The buyers
were told that that the old contract is good enough because anything

that's illegal won't be enforced. These contracts tend to also have very broad clauses blocking "anything with an aesthetic impact" and such, which is where the solar prohibition originated. One contract I've read itemized examples of prohibited installations, which included all forms of antennas and mentioned solar panels.

Locally, one planning department imposed some siting and support structure restrictions that effectively prevented installing of any solar panels. That apparently was accidental, but it took a year and an expensive legal action to get them to admit that they goofed.

One homeowner wanted a variance to install the solar panels very close to the property line. No CC&R's. The variance was denied because of neighbors protests. It went to court and he lost. Another tried to get his radio tower approved on the basis of it providing supports for his tower mounted solar panels. That also was denied.

The whole ruling is clearly biased to favor the homeowner. It is so biased that, if the HOA requires proof that your antenna is need to receive a signal, then the HOA must pay for any engineering costs that a site test would cost. Arguing distance from the transmitters (all of them) does not work because there might be sources of interference at your particular location. The test itself could be argued because it might not be performed under worst case conditions such as weather. The credentials of the tester could be questioned. Legal fees incurred by the HOA could be excessive. The HOA must pay for your legal expenses, I THINK even if you lose. This ruling clearly put the HOA's in their box. If the HOA lawywer knows the law (most of them do) they won't follow up on any threats. An HOA may try to use threats to get you to take it down anyway, hoping you are not aware of your rights. In that case, you can complain to the FCC. This practice is illegal.

Gentlemen,
I roughed out the antenna with the exception of the "twisted" pair
wires
All computor characteristics pretty much matched the measured
characteristics
of the antenna presently being evaluated.Wish I had more memory so the
segments could be increased.
I suspect it will take a couple of weeks before I can install the
tilting system, maybe longer
May do some qso,s while I wait for the equipment to arrive. Need to
get away from design work
for a few days.Everything I have hoped for so far has been acomplished
plus a few nice
surprises with respect to gain. May piddle with a dish reflector
iaddition n the mean time

OK, this time it's serious (well, mostly)...

The original meaning of "mandrel" seems to have been a rod-shaped tool, onto which metal can be forged or glass can be mo(u)lded. The mandrel is removed to leave a shaped cavity, and the mandrel can be used again. This meaning is obviously very old, and would have crossed the Atlantic with the Founding Fathers.

In the more recent context of coil winding, a mandrel is an object onto which the wire can be wound. Again, the mandrel is always removed - it is a tool, not part of the finished coil.

Some dictionaries note an alternative spelling, "mandril". This is an old English dialect pronunciation, just like "chisil". (I don't know any dialect-speaking blacksmiths, but can attest that "chisil" is still very much alive.)

The confusion with "mandrill" comes from the fact that a convenient mandrel of known size is the shank of... a drill.

The consequences of winding wire onto a mandrill - or indeed, onto a ferret - are Nature's way of punishing engineers who can't spell.

Dave said:
>

>
That's completely different from British engineering usage. We don't use
"coil form" at all. "Coil former" almost always means something that
remains inside the completed coil. If it were meant to be removed, that
would have to be made clear from the context.

Thinking 'cheap', a two-way equal-output cable TV passive
(non-amplified) splitter will have a signal reduction of around 4dB at
each port. This consists of an unavoidable 3dB (because the power is
halved) plus the circuit losses. Typical signal reduction figures are
3.5dB at 5MHz, 4dB at 500MHz and (say) 5dB at 1000MHz. For slightly

better performance at UHF, a satellite splitter might be a little better, but it may not perform at the lower frequencies.

The maker's spec for the isolation between the output ports will be about 25dB (theoretically infinite), but only when the source impedance (ie the antenna feed) is 75 ohms. If you have 50 ohms, it will be lower (theoretically, it can never better than ~21dB). This is more than enough.

Because of the unavoidable signal loss, I would hesitate about using an unamplified splitter. However, if you do use an amplified one, make sure that it has a good noise figure. Personally, if you don't need the two receivers to operate at the same time, I'd use a cable TV A/B switch.

An intriguing set of assertions. It would be good if you
could point out the equations that are in violation.

Is there an error in either
Ps(t) = Prs(t) + Pg(t)
or
Pg(t) = Pf.g(t) + Pr.g(t)

Both by derivation and by example, these seem to be true.

Do you disagree?

I would suggest that it is not 'obvious'. Some times the
energy from the reflected wave is being absorbed in the
source.

'Obvious' is often an excuse for an absence of rigour.

> But remember, we chose a special

Which assertion is wrong?
Ps(t) = Prs(t) + Pg(t) ?
Pg(t) = Pf.g(t) + Pr.g(t) ?

> > For example, if you were to do the same analysis,

You do use the words, but do not offer any equations that
describe the behaviour. The claim is thus quite weak.

> I repeat: The *only time* that reflected energy is 100%
> dissipated in the source resistor is when the two component

> All it takes is one case to prove the following assertion false:
>
> "Reflected energy is *always* re-reflected from the
> source and redistributed back toward the load."

I have never made that claim. So if that is your concern, I agree
completely that it is false.

My claim is that "the energy in the reflected wave can not usually be
accounted for in the source resistor dissipation, and that this is
especially so for the example you have offerred".

> You appear to think that if you can find many cases where
> an assertion is true, then you can simply ignore the cases

> where it is not true. I have presented some special cases
> where it is not true. It may be true for 99.9% of cases,
> but that nagging 0.1% makes the statement false overall.

Having never claimed the truth of the statement, I have
never attempted to prove it.

> Equally false is the assertion: "Reflected energy is
> always dissipated in the source resistor." The amount
> of reflected energy dissipated in the source resistor
> can vary from 0% to 100% depending upon network
> conditions. That statement has been in my article from
> the beginning.

But you have claimed special cases where the energy
is dissipated in the source resistor.

Ps(t) = Prs(t) + Pg(t)
and
Pg(t) = Pf.g(t) + Pr.g(t)
demonstrate this to be false for the example you have offerred.

> > So are you now agreeing that it is not the energy
> > in the reflected wave that accounts for the
> > difference in the heating of the source resistor
> > but, rather, the energy stored and returned from
> > the line, i.e. Pg(t)?
>
> I have already presented a case where there is *zero*
> power dissipated in the source resistor in the presence
> of reflected energy so your statement is obviously just
> false innuendo, something I have come to expect from
> you when you lose an argument.

Since it was a question, you were being invited to clarify
your position. But it begs the question:
When zero energy is being dissipated in the source resistor
in the presence of reflected energy, where does that reflected
energy go?

Recalling that by substitution
Ps(t) = Prs(t) + Pf.g(t) + Pr.g(t)
so that when the resistor dissipation is 0 for certain values of t
Ps(t) = 0 + Pf.g(t) + Pr.g(t)
= Pf.g(t) + Pr.g(t)
Pr.g(t) = Ps(t) - Pf.g(t)

Please provide equations that describe how the reflected energy is
split between the source and the forward wave.
For completeness, these equations should generalize to describe
the splitting of the energy for all values of t, not just those
where the dissipation in the source resistor is 0.

I've made no claims about destructive or other interference
so I am intrigued by what you say my analysis proves.

Could you expand on how my analysis "proves" that
"destructive interference energy is indeed stored in the
reactance of the network and dissipated later in the cycle
as constructive interference in the source resistor at a
time when the instantaneous source power equals zero."

I am not sure why you focus on the infinitesimally small
times when "the instantaneous source power equals zero".
Are you saying that at other times, an explanation other
than interference is needed?
Or does interference explain the flows of the energy
in the reflected waves for all times?

It would be good if you could provide the equations that
describe these flows, especially the ones describing the
storage of some of the energy from the reflected wave in
the reactance of the network.

It comes up in the conversation Art, I only rinse and repeat as necessary.

I'm still trying to wrap my mind around the antenna, I'm nowhere near ready to model it. So as to not make any ignorant mistakes, the antenna is counter-wound inductors, correct? and they are concurrently wound, as in they sort of weave against each other? And this is a full wave antenna? Do you use enameled wire, or what is the insulation? I'm assuming that this might be important in regards to VF.

I found some coax in the garage called RG58C/U E50032 AWM style 1354. It is silver coloured and not copper. Any one know if this coax is of good quality not?

I want to use some for the Cobwebb antenna and I want to make some coaxial traps for my wire antenna with it.

Thanks

Now small antennas can be made I would suggest to those encombered by
restrictions
to duplicate the following assembly so they may rejoin the hobby.
Obtain a 1/2 plastic pipe.
Purchase two reels of dog fence wire which is pre wound twin wire
Solder the wires of each reel such that it is now a continuos wire.I
used the 20 gauge form from E bay($24)
With the joint at the back of the plastic pipe turn the right hand
side one loop and then the other side one loop but in the opposite
direction.
Procede until you have a wrapped pipe of say a 6 foot length.
Obtain a hula hoop from a store and remove the joining plug.
Push the windings off of the plastic pipe and slide it on the hula
hoop
untill it is full.Replace the plug and connect the transmission lines
to one of each
of the wound wires and solder together
the remaining two wires. Locate resonant points for all bands and
connect to a rotary switch of your choice
for connection for future band use.This antenna will be useable for
all of the top band and upwards.
Each tap supplies enough coverage for any particular band so no
externerl tuning components are required.
As a simple hoola hoop this can be left anywhere in the yard or placed
easily into the attic
where it can only be seen as a childs toy which are always left around
in sight of nosy niebours.
Since it is a closed loop there is little danger of television
problems or high arcing voltage and you may now join the hams on any
band. If you require the loop to be smaller twist it into a figure
eight shape befor replacing the plug.As a listening antenna it can be
placed on top of the tower where it is situated away from ground
noise.

This version is quite light and is an excellent candidate for use via
turning and tilting on a
security observation assemble which allows you to probe the polarity
of incoming signals as well as
cancelling noise that comes from different directions in the loft.
These are now becoming available as cameras get smaller where the
don't need heavy motors e.t.c Keep it as small as possible so it

doesn;t tip the mechanism and break it.
The antenna by the way can be twisted in different directions as long as one keeps it symetrical (in equilibrium)
One doesn't have to buy a hoola hoop. Common garden water pipe can be used which makes it more inconspicuious when left outside with the remaining water pipe.
Regards
Art

Art,
"Since it is a closed loop there is little danger of television
problems or high arcing voltage..."

That's news to me Art. I've found that closed loops can produce TVI/
RFI quite well.

And while an antenna of this sort might be capable of letting you
produce a signal on a particular band, it certainly won't be adequate
in most cases. A dummy-load can do the same thing, no switching
required.

None of this means that there aren't a few options available for those
with restrictions! Those options are not going to be 'good' ones,
just adequate,sort of. The root of the problem with living in a
restricted area is that you agreed to those restrictions when you
chose to live there. So, live with them, or move, or change those
restrictions.

Keith Dysart wrote:
> My claim is that "the energy in the reflected wave can not usually be
> accounted for in the source resistor dissipation, and that this is
> especially so for the example you have offerred".

The instantaneous example to which you are referring does
not meet my special case requirement of *ZERO INTERFERENCE*
so your above statement is just another straw man and is
thus irrelevant to my claim. But you already know that.

I agree with you that "the energy in the reflected wave can
not usually be accounted for in the source resistor dissipation."
I have stated over and over that the reflected energy
dissipation in the source resistor can range from 0% to 100%.

My claim is that when the special case of *ZERO INTERFERENCE*
exists between the two voltages superposed at the source resistor,
then 100% of the reflected energy is dissipated in the source
resistor. You have not provided a single example which proves
my claim false.

The test for *ZERO INTERFERENCE* is when, given the two
voltages, V1 and V2, superposed at the source resistor,

(V1^2 + V2^2) = (V1 + V2)^2

None of your examples have satisfied that special case
condition. My average reflected power example does NOT
satisfy that condition for instantaneous power!

Here's the procedure for proving my claim to be false.
Write the equations for V1(t) and V2(t), the two instantaneous
voltages superposed at the source resistor. Find the time
when [V1(t)^2 + V2(t)^2] = [V1(t) + V2(t)]^2. Calculate
the instantaneous powers *at that time*. You will find that,
just as I have asserted, 100% of the instantaneous reflected
energy is dissipated in the source resistor.

Until you satisfy my previously stated special case condition
of *ZERO INTERFERENCE*, you cannot prove my assertions to be
false.

Keith Dysart wrote:
> I am not sure why you focus on the infinitesimally small
> times when "the instantaneous source power equals zero".

:-) :-) That was my exact reaction when you wanted to
focus on the infinitesimally small times associated
with instantaneous powers. :-) :-) You are to blame
for that focus, not I.

It only takes one example to prove your claims wrong.
I didn't want to focus on instantaneous power at all
but you insisted. Now that your own techniques are
being used to prove you wrong, you are objecting.

At the time when the instantaneous source power is zero,
the only other sources of energy in the entire network
is reflected energy and interference energy. That's
a fact of physics.

You have gotten caught superposing powers, something
that every sophomore EE knows not to do. I repeat:
The only time that power can be directly added is
when there is *ZERO INTERFERENCE*. The test for
zero interference is: (V1^2 + V2^2) = (V1 + V2)^2

Actually, with modern high quality receivers (which may not include the
$40 DTV to NTSC converters), they use a rake receiver to coherently
combine the multiple paths, so it's very likely that you'd get a better
signal with digital (i.e. the receiver would lock and you'd get ANY
output) than with analog in a multipathy, but not faint signal environment.

One of the design goals for DTV was to be multipath immune.

Note that in Europe, they actually transmit the identical signal from
multiple transmitter sites, guaranteeing multiple arriving signals with
different timing. Different modulation scheme, but the same multipath
issues. The same has been proposed for use in the US

However, with DTV, signal strength is more of an issue,mostly because
there isn't a "degraded mode" like there is with analog. Most viewers
are willing to tolerate remarkably degraded signals on an analog
channel, so folks are used to being able to receive a TV signal well
beyond the nominal service boundary. With digital, either you got it or
you don't. Some gain in the antenna helps..

I am hoping that because of the narrow filter requirements of ham
radio

a fast acring multipath antenna switch would allow the dominant polarisation to over rule all otherssince the ear can only accept a few samples at a time.

Well, of course, you do when you argue with me. For instance, you believe that reflections can occur when the reflections see a reflection coefficient of 0.0, i.e. a source resistance equal to the characteristic impedance of the transmission line. This obviously flies in the face of the wave reflection model. When you cannot balance the energy equations, you are arguing with the conservation of energy principle.

I have use std house wiring,enamelled magnet wire and simple buried
dog wire.
which I believe has the lowest insulation. Min wire I have used is #22
because the wire is not meant to support anything so 100%
of fused value seems to be o.k.
I have taken the windings off of the former but it is lacking in
strength.
I am using a wood lathe so that I can wind at 90 overlap of the wire
which will leave small holes
and will be stronger.
I made a machine to do this in the U.k. before I came over which had
no holes and was made of glass fibre tape.
I sold the machine which I used for lampshades before I came ove.
Prior to that shades were of monofiliament wound in single direction.
The machine was really for making an equivalent fuel containers on
the Atlas rocket so I made one for myself out of bycycle chain and
infra red heaters and mad some pocket money.
All of these I have tuned up with 100 watts

Why not just wind a mirror image on your wlky talky antenna:
That way you are not using your body as a heat sink!s

The hard part of winding it on a mandrill is getting it to stand still.

It may be tinned copper - giving it the silver color - and making it easier
to solder..
here's what a ham normally does : TIAS (Try It And See)

If you can find the Manufacturer's name, you may be able to look up the
'loss per mft' for different freqs on their website.

That's why you need the mandrel.. you whack the mandrill over the head (pretty hard), then, while it's stunned, you quickly wind the wire on it.

Of course, you need to move fast to remove your winding before the mandrill regains consciousness. They're pretty big and strong, and have BIG teeth.

On the other hand, if you are winding on a Mandrell, they understand spoken language. You might be able to just explain what you're doing, and she (or he) might sit still for the process. Mandrells also have much smaller teeth than mandrills, and aren't nearly as strong, so if they do object during the winding process, your risk of injury is less.

In a previous iteration, I had accepted that your claim only
applied when there was zero interference. I converted that to
the particular values of wt for which your claim aaplied,
e.g. 90 degrees.

I then restated your claim as applying only at those particular
times and not at other points in the cycle, but you were
unhappy with that limitation.

So you have to choose...
Does it only apply at those particular points in the cycle
where wt is equal to 90 degrees or appropriate multiples?
(A restatement of only applying when there is no interference.)
or
Does it apply at all times in the cycle?

Could you state the claim that you think you are proving
wrong?

> I didn't want to focus on instantaneous power at all
> but you insisted. Now that your own techniques are
> being used to prove you wrong, you are objecting.

If you wish to have your equalities apply at only selected
points within the cycle, that works for me.

It only fails when you make the assertion that
for the circuit under consideration, the energy in
the reflected wave is dissipated in the source
resistor.

> At the time when the instantaneous source power is zero,
> the only other sources of energy in the entire network
> is reflected energy and interference energy. That's
> a fact of physics.
>
> You have gotten caught superposing powers, something
> that every sophomore EE knows not to do.

Could you kindly show me where?

The two expressions in which I have summed power are
Ps(t) = Prs(t) + Pg(t)
and
Pg(t) = Pf.g(t) + Pr.g(t)

You have not previously indicated that either of these
are incorrect. Please take this opportunity.

> I repeat:
> The only time that power can be directly added is

> when there is *ZERO INTERFERENCE*. The test for
> zero interference is: (V1^2 + V2^2) = (V1 + V2)^2

Surely you overstate. Powers can be directly added whenever you have a system with ports adding and removing energy from the system. Conservation of energy says that the sum of the energy being stored in the system is equal to the sums of all the ins and outs at the ports. There are no conditions on the ports adding or removing energy.

You won't find anywhere that I said that. In fact, I
was quite pleased that I had helped you relearn this
tidbit from your early education which previous posts
made clear you had forgotten. Did you eventually look up "reflection",
"lattice" or "bounce diagram"?

> This obviously

But I notice that you have not yet indicated which
energy equation I may have written that was unbalanced.
You do have a nack with unfounded assertions, don't
you?

According to the Belden catalog
(http://www.belden.com/pdfs/03Belden_Master_Catalog/06Coaxial_Cables/06Coaxi
al_Cables.pdf page 77, Trade No 8262), it's a better grade of RG58/U:

20 AWG stranded (19x33) tinned-copper center conductor, solid polyethylene
dielectric, tinned-copper 95% braided shield, non-contaminating PVC jacket.
The last part is likely the most important factor for outdoor use. I
believe E50032 is a manufacturer's part number (apparently, not Belden).

There are no limitations. If zero interference exists,
then 100% of the reflected energy is dissipated in
the source resistor.

Not only at selected points within the cycle but
also for average values. If zero average interference
exists then 100% of the average reflected energy is
dissipated in the source resistor which is the subject
of my Part 1 article. If the instantaneous interference
is zero, 100% of the instantaneous reflected power is
dissipated in the source resistor.

I repeat: When zero interference exists, 100% of the
reflected energy is dissipated in the source resistor.

Why should I waste my time finding your conservation of
energy violations?

I repeat: When there exists zero interference, 100%
of the reflected energy is dissipated in the source
resistor. Since you think you provided an example where
that statement is not true, your example violates the
conservation of energy principle.

3418. Directional antenna in the 215 to 218 MHz band

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-20 05:44:50 UTC
From: usmcbrat <president@whitehouse.gov>
Message-ID: <mRmEj.7673$%Y2.2092@trnddc08>
Source record: 26890

Hi Folks:

I'm looking to make a directional antenna in the 215 to 218 MHz band (215 if that's too broad), used for location of dementia patients who have wandered away from their caregivers. I'm a volunteer with an organization that locates these people. They wear a tiny transmitter which emits a chirp that can be heard from 1-2 miles on the ground and 8-10 miles via helicopter.

I'm somewhat new to the program, and I'd like to do some investigation on my own regarding antenna types that would be useful, and I hope you'll all grant me a few questions.

My needs are this.... the antenna must be as directional as possible. It must be most efficient in the 215 to 218 MHz band 215 is what our patients are on right now, though after we fill up that range we have licensed through 218 MHz. It must be easy for an individual to carry, and portable enough to carry through any type of terrain. It must be shaped in such a way that it's relatively safe and easy to use in an enclosed area, either in a helicopter or a car. Currently the agency is using a 4 element Yagi, which works well, but has the drawback of being a real eye-poker when used in close quarters, and in fact the California Highway Patrol will not allow them to be used in their helicopters because of that reason.

One of our Search & Rescue guys built his own 4 element Quad Yagi out of some 1/2" PVC pipe and other parts that are readily available at any Home Depot. It has greater sensitivity than our stock antenna, and the CHP has said that it's OK to use in their helicopters. Rather than 4 horizontal straight beams it has 4 squarish beams, with no points to poke people's eyes out. I'm still waiting to get the plans from him for that antenna, and I though that in the meantime I'd ask in here if any of you had some interesting leads for me to follow.

Many thanks!

3419. Re: Directional antenna in the 215 to 218 MHz band

Source record: 26891

Clarification:

216 MHz is what we're using now. We're getting away from 215 because of interference with digital TV.

Hi USMCbrat,

Research the Google newsgroups (for this newsgroup specifically)
archive with the keyword "foxhunt." There are more issues than just
directionality to be considered.

> the source resistor.

Sentence one says "no limitations". Sentence two specifies a
limitation. But your paper did provide that limitation and
indicated that circuit (Fig 1-1) with a 45 degree line was
an example which satisfied that limitation.

But in subsequent discussion you have waffled about whether,
for the circuit in Fig 1-1, "100% of the reflected energy is
dissipated in the source resistor" is applicable for all
time or only for those instances when the source voltage is
equal to 0.

Could you clarify whether your claim for the circuit of
Fig 1-1 applies to all time, or just to those instances
when the source voltage is 0.

On Mar 20, 12:34 am, Cecil Moore <nos...@w5dxp.com> wrote:

> dissipated in the source resistor.

Perhaps this has clarified. So you are only claiming that
reflected energy is dissipated in the source resistor at
those instances when the source voltage is zero. Good.

Now as to averages: Averaging is a mathematical operation
applied to the signal which reduces information. I do agree

that the increase in the average dissipation in the source
resistor is numerically equal to the average value of the
reflected power. But this is just numerical equivalency.
It does not prove that the energy in the reflected wave
is dissipated in the source resistor. To prove the latter,
one must show that the energy in the reflected wave, on
an instance by instance basis is dissipated in the source
resistor because conservation of energy applies at the
instantaneous level.

And I have shown in an evaluation of the instantaneous
energy flows that the energy dissipated in the source
resistor is not the energy from the reflected wave.

> I repeat: When zero interference exists, 100% of the
> reflected energy is dissipated in the source resistor.

But only at those instances where the source voltage is
zero.

On Mar 20, 12:50 am, Cecil Moore <nos...@w5dxp.com> wrote:

Mostly to prove that my analysis has an error.

> I repeat: When there exists zero interference, 100%
> of the reflected energy is dissipated in the source
> resistor. Since you think you provided an example where
> that statement is not true, your example violates the
> conservation of energy principle.

But if there is no error in my analysis (and you have not
found one), then perhaps you should examine whether the
clause "When there exists zero interference, 100% of the
reflected energy is dissipated in the source resistor"
is in error. Sometimes one has to re-examine one's deeply
held beliefs in the light of new evidence. It is the only
rational thing to do.

3424. Stealth Loop antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-20 13:30:34 UTC
From: Buck <usenet01@lumpuckeroo.com>
Message-ID: <4jo4u3lj16tlh5rhkc253baa3vv21a92b7@4ax.com>
Source record: 26896

This is an interesting antenna. It is a mobile stealth magnetic loop
antenna.

http://stealth.ae/plugins/custompages/detinf.php?id=372&id_categories=136

I watched the video and checked out the details. The antenna is
basically a loop with the roof of the car (the bottom of the luggage
rack) as the ground side of the loop, the antenna goes up, folds over
the top and back down to the other side of the roof where it feeds
thru a high voltage vacuum variable capacitor back to ground.

```
---------------------------
| |
|_ |
| |( coax conx) = Capacitor
| -|_____________|
^ (roof)
^
(feed)
```

I am not as good an artist as some of you, but here is my graphic
The coax feeds with a gamma? and is tuned by a stepper motor tuning
the vacuum variable cap. Depending on which of the three models, it
operates from 1.5-10 MHz, 2.7-15.5 MHz, or 4.5-22 MHz at up to 150
watts.

The technical notes have more interesting details:
http://stealth.ae/plugins/custompages/articles.php?id=10

It seems to me a homebrew version could be made for base use such as
for those in restricted homes. Placed on the peak of the house, the
ground side could be a wire across the top of the peak and the loop
lift up during use so it would not attract too much attention to the
neighbors.

I wonder what the size and cost of the Vacuum variable is to make a
similar antenna??

Keith Dysart wrote:
> Sentence one says "no limitations". Sentence two specifies a
> limitation.

Semantic games. There are no limitations within the
stated boundary conditions just like any number of
other concepts.

> Could you clarify whether your claim for the circuit of
> Fig 1-1 applies to all time, or just to those instances
> when the source voltage is 0.

There are no claims regarding instantaneous power in
Fig 1-1 or anywhere else in my web article. All the
claims in my web article refer to *average* powers and
the article states exactly that. For the purpose and
subject of the web article, the subject of instantaneous
power is just an irrelevant diversion. No other author
on the subject has ever mentioned instantaneous power.
Given average values, time doesn't even appear in any
of their equations. Apparently, those authors agree
with Eugene Hecht that instantaneous power is "of
limited utility".

Here's my claim made in the article: When the *average*
interference at the source resistor is zero, the *average*
reflected power is 100% dissipated in the source resistor.
I gave enough examples to prove that claim to be true.
Since the instantaneous interference averages out to
zero, this claim about *average* power is valid.

When Tom, K7ITM, asserted that the same concepts work
for instantaneous power, I took a look and realized that
he was right. One can make the same claim about instantaneous
power although I do not make that claim in my web article.

When the instantaneous interference at the source resistor
is zero, the instantaneous reflected power is 100% dissipated
in the source resistor.

> Perhaps this has clarified. So you are only claiming that
> reflected energy is dissipated in the source resistor at
> those instances when the source voltage is zero. Good.

I am claiming no such thing. Please cease and desist with
the mind fornication, Keith. You cannot win the argument
by being unethical.

> Mostly to prove that my analysis has an error.

I have pointed out your error multiple times before, Keith,
and you simply ignore what I say. Why should I waste any
more time on someone who refuses to listen?

One more time:
Over and over, you use the equation Ptot = P1 + P2 even
though every sophomore EE student knows the equation is
(usually) invalid. The valid method for adding AC powers is:

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(A)

The last term is called the interference term which you
have completely ignored in your analysis. Therefore, your
analysis is obviously in error. When you redo your math
to include the interference term, your conceptual blunders
will disappear. Until then, you are just blowing smoke.

Source record: 26898

I have some questions about the choke and feed line on the Cobwebb.

Does the co-axial choke balun work better if the cable is wound on top of each other into a tube shape rather than just winding it round and zip tying it together in a round bundle?

Can I attach a SO239 Chassis socket to the end of the box where the coax enters and then plug a PL259 into that for the feeder or will the socket allow current to bypass the choke balun and enter the feed line?

Thanks

For the first 90 degrees of time, the circuit can be represented as

>> Rs Vg Vl
>> +----/\/\/-----+----------------------+
>> | 50 ohm |
>> | /
>> Vs \ 50 ohm resistor
>> 100v RMS /
>> | \
>> | |
>> +--------------+----------------------+

After 90 degrees of time has passed, the circuit can be represented as

>> Rs Vg Vl
>> +----/\/\/-----+----------------------+
>> | 50 ohm |
>> | |
>> Vs ---
>> 100v RMS --- 50 ohm inductive
>> | |
>> | |
>> +--------------+----------------------+

>> gnd

The sudden switch in circuit design at time 90 degrees is not unique to start up, but is true for any adjustment made to Vs and any returning wave from the shorted stub,. As a result, a true stable circuit will never be found unless some voltage adjustment is allowed for the 90 timing shift caused by the shorted stub. Keith (in his analysis of the circuit) recognizes that Vs drives into a reactive circuit.

If we want to understand how constructive and destructive interference act to cause a 50 ohm resistor to evolve into a 50 ohm capacitor, then we need to examine how traveling waves might do this. It would be nice to have a formula or wave sequence that fully addressed this evolution.

From circuit theory, we have the inductive reactance of a short-circuited line less than 1/4 wavelength long is

XL = Zo * tan (length degrees)

= 50 * tan(45)

= 50 ohms

From traveling wave theory, we would have the applied wave from the source arriving 90 degrees late to the stub side of resistor Rs. This ignores the fact that current must already be passing through resistor Rs because voltage has been applied to Rs from the Vs side 90 degrees earlier. Whoa! Things are not adding up correctly this way!

We need to treat the wave going down the 50 ohm line as a single wave front. The wave reverses at the short-circuit, reversing both direction of travel and sign of voltage. When the wave front reaches the input end, 90 degrees after entering (for this case), the voltage/current ratio is identical to the starting ratio (the line was 45 degrees long, tan(45) = 1), and the returning voltage directly adds to the voltage applied from Vs. As a result, the current flowing through Rs will increase, and Vs will see a changed (decreased) impedance.

After 90 degrees of signal application, we should be able to express the voltage across Rs as

Vrs(t) = Vs(t) - Vg(t) + Vref(t)

Vs(t) = Vs(wt + 90), Vg(t) = Vs(wt + 90)/2, Vref(t) = Vs(wt)/2

Substitute so

Vrs(t) = Vs(wt + 90) - Vs(wt + 90)/2 + Vs(wt)/2

= Vs(wt + 90)/2 + Vs(wt)/2

Allow Vs to be represented by a sine wave, we have

2Vrs(t) = Vs*sin(wt + 90) + Vs*sin(wt)
= 2Vs*(sin(wt + 45)(cos(45))

Vrs(t) = Vs(sin(wt + 45)(cos(45))

Vs is defined as 100v RMS, which equals 100 * 1.414 = 141.4v Peak. The maximum voltage would occur when the sin term was 90 degrees and equals 1, which would occur at wt = 45 degrees. We would have

Vrs(45) = 141.42 * sin(90)(cos(45)
= 141.42 * 1 * 0.7071
= 100v

Now consider the current. After the same 90 degrees of signal application, we should be able to express the current through Rs as

Irs(t) = Is(t) + Iref(t)

Is(t) = Is(wt + 90), Iref(t) = Is(wt)

The reflected current has been shifted by 90 degrees due to the reflection so we must rewrite Iref(t) to read

Iref(t) = Is(wt + 90)

Substitute,

Irs(t) = Is(wt + 90) + Is(wt)

Allow Is to be represented by a sine wave, we have

Irs(t) = Is*sin(wt + 90) + Is*sin(wt)

= 2*Is(sin(wt + 45)(cos(45))

How do we find Is? Is is the initial current found by dividing the applied voltage at peak (141.42v) by the initial resistance (100 ohms).

Is = 141.42/100 = 1.4142a

The maximum current would occur when the sin term was 90 degrees and equals 1, which would occur at wt = 45 degrees. We would have

Irs(t) = 2*Is(sin(wt + 45)(cos(45))

= 2 * 1.4142 * 1 * 0.7071

= 2a

These results agree with the results from Keith and from circuit theory.

We have a theory and at least the peaks found from the theory agree with the results from others. How about Cecil's initial question which is
>> At the zero-crossing of Vs, Ps(t) = 0, i.e. the source
>> is supplying zero watts at that time but Prs(t) = 100w.
>> Where is the 100 watts coming from?

We will use the equation

Vrs(t) = Vs(t) - Vg(t) + Vref(t)

Vs(t) = Vs(wt + 90), Vg(t) = Vs(wt + 90)/2, Vref(t) = Vs(wt)/2

The challenge looks at the time when Vs(t) = Vs*sin(wt + 90) = 0, which occurs when wt = -90. When wt = -90, all the power to the source resistor Rs is from the reflected portion described as Vref(t) = Vs(wt)/2. The voltage across Rs would be

Vrs(-90) = Vref(-90)
= Vs*sin(-90)/2
= 141.4/2
= 70.7v

The power to Rs would be (Vrs^2)/50 = (70.7^2)/50 = 100w, all coming from the reflection.

In summary, power to the resistor Rs comes via two paths, one longer than the other by 90 degrees (in this example). The short path is the series path of two resistors composed of the source resistor Rs and the input to the 50 ohm transmission line measured by Vg. The long path is the series path of one resistor Rs and one capacitor composed of the shorted transmission line. Both paths are available at all times. Power flows through both paths to Rs at all times, but because of the time differential in arrival timing, at some point Rs will receive power only from Vs, and at another point, receive power only from Vref.

Not sure about the higher frequencies but in the HF band we absolutely need
an antenna coupler that matches the impedance to the selected frequency. If
a coupler fails we can barely throw a signal a few miles whereas when the
coupler does it's job we can bounce a signal off of the ionosphere at night
for a few thousand miles.

I'm looking for suggestions for the Strange Antenna Challenge this Memorial Day week-end. One guy used a pair of back-to-back trucks to make a dipole, and one guy loaded up a sports stadium. A group in Atlanta used an Extension Ladder on 20M and that worked well, but that seems a little less strange than I'd like. It almost looks like a regular antenna when it's standing straight up.

I want something that doesn't look like an antenna (one guy suggested hoisting a BBQ grill into the trees, but I'm sure that wouldn't work well on 20M). I want something that can be adjusted to be somewhat near resonance without a tuner.

Ideas?

Eric

Good job, Roger. Let's simplify the equation through
substitution.

Let V1(t) = [Vs(t) - Vg(t)]

Let V2(t) = Vref(t)

Vrs(t) = V1(t) + V2(t)

> The power to Rs would be (Vrs^2)/50 = (70.7^2)/50 = 100w, all coming

Yes, because when Vs(t)=0, there is zero instantaneous
interference.

What Keith is missing is that:

Vrs(t)^2 = [V1(t) + V2(t)]^2 NOT= V1(t)^2 + V2(t)^2

In his math, Keith is asserting that since

Prs(t) NOT= P1(t) + P2(t), then the reflected power is not
being dissipated in the source resistor. But every sophomore
EE knows NOT to try to superpose powers like that. Roger,
I'll bet you know not to try to superpose powers?

Since Keith doesn't listen to me, would you pass that
technical fact on to him?

When Keith uses the correct equation:

Prs(t) = P1(t) + P2(t) +/- 2*SQRT[P1(t)*P2(t)]

he will see that the equation balances and therefore
100% of the reflected energy is dissipated in the
source resistor since the interference term averages

out to zero over each cycle.

Hi Buck,

Take your cue from the page. Multiply by Q and you have your ratings
(add a safety factor). Go to eBay and look at the prices. Place
order and wait for the mail. Assemble. Operate.

I suspect you already know that and are seeking solutions that border
on fantasy. Art has revealed the characteristics of his 160M antenna
(it takes only scaling to your favorite band) to obtain remarkable
results (he knows what they are, but hasn't actually tested one).

Fantasy publication is common enough here to satisfy any taste: You
can get at least 3dB more "efficiency" (emphasis due to its new,
tailored definition). You enjoy new equilibriums not formerly
available in common and ordinary antennas (such as those drab and
outdated models found at the web page you provided). You can discover
added signal strength from Gaussian principles (it's not just about
gain anymore). Find the hidden power of polarization unknown to the
general antenna marketplace. Size is of no consequence with
counterwound coupling. Q is no longer the irritating limitation it
once was. Marvel at hiding it in a hula hoop in the grass so the
neighbors don't suspect it as an antenna. No RFI either! Mount it on
a steerable camera mount so you can point it (and the camera) into
neighbor's windows.

Advantages galore to be found that were previously unthinkable with
those huge and cumbersome antennas that could only communicate with
half the world.

>for a few thousand miles.

That's certainly true at the transmitting end. A good impedance match is needed in order to enable the transmitter to deliver power effectively into the antenna, from whence it can be radiated.

It's rather less true at the receiving end, at least in the lower-frequency HF bands. In these bands, the ability to receive a usable signal is often dominated by the amount of natural and man-made noise in the band, and not by the receiver's own self-generated noise. Even with a serious impedance mismatch between the antenna and the receiver, enough signal reaches the receiver front-end to overcome the receiver's own internal noise.

If you happen to live in an area which is blessed by a very low background-noise level (e.g. out in the country, away from power lines) and you're DXing in the HF bands, then a good impedance-matched antenna will let your receiver take best advantage of the low noise level.

If you're SWLing in a city, surrounded by power lines and electric motors and neon lights and computers, the background noise level is going to be much higher, and the weak distant stations will be drowned out by the noise anyhow... and an inefficiently-matched antenna such as a whip or longwire will give you enough signal to hear the stations which are _not_ drowned out by the noise.

As an example - if your receiver has decent sensitivity, and a low internal noise level, you may find that you can hear a signal with decent audio quality all the way down to S0 or below (if there's no noise obscuring it). You then find that with an impedance-matched antenna the band's background noise is S6 or so. Assuming that you can make use of a signal which is somewhat below the broadband noise level, let's say that you decide you can copy stations whose own individual signals are S5 or better, and that lower-level signals are blanketed by the noise.

At this point, you realize that you can use an antenna which is 5 S-points (nominally, 30 dB) less efficient, and still receive the same set of stations. With a less efficient antenna, the stations' signals will be weaker... but so will the external band noise, by the same

ratio, and thus the signal-to-noise ratio of each station will remain unchanged.

As an example, my ARES/RACES group has a multiband HF setup in our city's police and fire admin building, which is downtown near the main commercial-and-restaurant street and the light-rail system. We have a trap-dipole antenna strung up above the building's roof. On the 80-meter band, the broadband noise level across the whole band is rarely less than S9! We could probably receive the same set of stations using an antenna consisting of two coat-hangers and some damp string!

3440. "V" Dipole Antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-20 20:34:40 UTC
From: WB8YKH <lguyot2@gmail.com>
Message-ID: <90e29335-7c89-4f45-b9df-cd7ee8a4bbf8@n77g2000hse.googlegroups.com>

There is much literature on the inverted "V" antenna but I've found nothing on a "V" Dipole Antenna. Can someone help me with resources or information on installation and effects of a "V" Dipole? In my current location I am unable to raise my center point much more than 15 feet off ground. However I can raise the endpoints 30+ feet. Before I go through much effort on the install I'd like to know what kind of performance I can expect. Thank you for your insights!

Most dipoles are of the V type, having that weight in the middle and
all. Your dipole will work okay, go for it.

What is the reason for the center being half as high as the ends? There
will be some droop always, unless you place too much tension on the
wires - don't do it. It looks nice and all, but that antenna's probably
going to come down before too long.

Technically, there will be some differences between it and a straight
dipole. Just not that huge, and hey, that is what your situation allows!
If you give me your lengths and frequencies you are using, I can model
it for you.

It will have a pattern very similar to a horizontal dipole at a height
equal to the height of your antenna 1/3 of the way out from the center.
If the center is at 15 feet and ends are at 30 feet, it'll have nearly
the same pattern as a horizontal dipole at 20 feet.

Impedance-wise, it'll act nearly the same as an inverted vee.

The reason for wanting to know the above is, I want to use RG58 inside the box and then run RG213 up to the box for the feeder from the radio. I don't want to do this if the S0239 socket is going to allow the feed line to radiate. Can any one please advise?

Many thanks

Coax feedlines are no more or less balanced than twinlead lines. Common mode current can occur on either, and for the same reasons, and either can be balanced by suppressing or avoiding creation of common mode current. The topic is discussed in more detail at http://eznec.com/Amateur/Articles/Baluns.pdf.

Feedline radiation is a consequence of common mode currents. Common
mode currents are a consequence of unbalance. Coax systems are
unbalanced. To correct this, you need to choke the coax line at the
feed point, and probably again a quarterwave away from the feedpoint.

:-) I saw the comment about "narrow-banding" the images. They were
perhaps a little more than we needed, but it was nice to have
something we could actually see. They did not take very long to
download here, but someone with a slow connection may have troubles.

One comment: usually you do not need much voltage gain. It is enough
to get power gain with the FETs. That is, the received signal voltage
across the gap of the loop, as resonated by the capacitors, should be
high enough to be used with a good receiver. The problem is that the
impedance is very high there. But that same high impedance makes for
easy oscillation. From what you posted, it sounds like maybe you have
identified an oscillation. If the AGC voltage is low enough, does the
oscillation stop? The amplifier I built used two stages, an FET input
stage and a buffer stage, and it had very low voltage gain--I am
remembering about 3:1 or only 10dB, and maybe only 1:1 or 0dB
including the output transformer, but quite a bit of power gain since
it transformed the high loop impedance down to 50 ohms for the
feedline.

Also, there should be no need for the RF chokes from the gate-1 to
source, if the loop is grounded at the bottom. If the loop is
grounded at the bottom, the loop plus the RF chokes will short out the
source-to-ground resistor. Maybe there is not a need to raise the
source voltage above DC ground potential anyway. Also, it may help to
NOT bypass the sources to ground, to allow some negative feedback.
That may help stabilize the amplifier.

If other things occur to me, I will post them...

Cheers,
Tom

> I'll bet you know not to try to superpose powers?

Using circuit theory, at the peak under steady conditions, we have
141.4v applied to 70.7 ohms which gives a current of 2a. The 70.7 ohms

is sqrt(50^2 + 50^2). Two amps flowing through Rs = 50 ohms, the power to Rs is (2^2) * 50 = 4 * 50 = 200w.

Using your simplified equation for the voltage across Rsj

Vrs(t) = V1(t) + V2(t)

Vrs(t) = V1*sin(wt + 90) + V2*sin(wt)

In our case, V1 = V2 because both voltages are developed over a 50 ohm load. As a result, in our case, 100w will be delivered to Rs both at wt = 0 and wt = -90, two points 90 degrees apart. If we are looking for the total power delivered to Rs, then it seems to me like we SHOULD add the two powers in this case. This recognizes that power is delivered to Rs via two paths, each carrying 100w. Alternatively, we could add the two voltages together to find the peak voltage, and then square that number and divide by the resistance of Rs. Both methods should give the same result.

So it looks to me like Keith is right in his method, at least in this case.

> 100% of the reflected energy is dissipated in the
> source resistor since the interference term averages
> out to zero over each cycle.

I am still uncomfortable with my summary statement that both paths, the long and short, are available and active at all times. On the other hand, it is consistent with your advice that the waves never reflect except at a discontinuity. The conclusion was that 100w is delivered to Rs via each path, with the path peaks occurring 90 degrees apart in time. Surprisingly, 100 percent of the reflected energy is ALWAYS absorbed by Rs. There is no further reflection from Vs or Rs.

This is counter intuitive to me. I like to resolve the circuit into one path, one wave form. We do that with circuit analysis. With traveling waves, we frequently have two or more paths the exist independently, so we must add the powers carried on each path, just like we add the voltages or currents. (But watch out and avoid using standing wave voltages or currents to calculate power!)

Most surprising to me is the observation that my beginning statement (from my previous post) about the circuit evolving from a circuit with two resistive loads, into a circuit with a resistive load and

capacitive load, is really incorrect. Once steady state is reached, BOTH circuits are active at the same time, forming the two paths bringing power to RS. Using that assumption, we can use the traveling waves to analyze the circuit.

Do a search for "tape measure antenna". It is a simple to build yagi
antenna made of pvc pipe with elements made from a metal measuring
tape. You can rescale it to your frequency.

Yes. It's stop. my main reason for this antenna is make very narrow
antenna for city. I can't receive to my receiver almost nothing by big
nose from computers, lamps and other things. But looks like this
antenna did not help. Its amplify narrow-band noise. And even add more
noise when oscillated.

The amplifier I built used two stages, an FET input

> Since the instantaneous interference averages out to
> zero, this claim about *average* power is valid.

Without prejudice to the accuracy of the above, let us
explore a bit.

We know that conservation of energy requires that the
energy flows balance at all times, which means that at
any instance, the flows must account for all the energy.

Analysis has shown that when examined with fine granularity,
that for the circuit of Fig 1-1, the energy in the reflected
wave is not always dissipated in the source resistor. For
example, some of the time it is absorbed in the source.

Now when the instantaneous flows are averaged, it is true
that the increase in dissipation is numerically equal to
the average power for the reflected wave. But this does
not mean that the energy in the reflecte wave is dissipated
in the source resistor, merely that the averages are equal.

Now you qualify your claim with the term "*average* power".
You say "the *average* reflected power is 100% dissipated in
the source resistor."

But the actual energy in the reflected wave is not dissipated
in the source resistor. So what does it mean to say that the
average is?

Unfortunately you struck the sentence which I paraphrased
and then failed to explain which parts of it I may have
misinterpreted. That does not help. It would have been
more valuable for you to rewrite the original sentence
to increase its clarity.

Which of the two needs the 'cos' term?

Ps(t) = Prs(t) + Pg(t)
or
Pg(t) = Pf.g(t) + Pr.g(t)

In fact neither do. They both stand quite well on their own.
Both are so correct, that they apply for any voltage function
provided by the source. What would you propose to use for cos(A)
when the source voltage function is aperiodic pulses? Fortunately,
the 'cos' term is not needed so the question is completely moot.

Non-the-less do feel free to offer corrected expression that include
the 'cos(A)' term.

> The last term is called the interference term which you
> have completely ignored in your analysis. Therefore, your

The math holds as it is. But I invite you to offer an alternative
analysis that includes cos(A) terms. We can see how it holds up.

If you can't, then you should definitely reconsider who is
'blowing smoke'.

...Keith

```

Just to ensure clarity, you are using a different convention for terms
and
signs than I do.

For me, Vg(t) is the actual voltage at point Vg. In terms of forward
and

reverse: Vg(t) = Vf.g(t) = Vr.g(t), meaning the actual voltage at
point
g is sum of the forward and reverse voltage at point g.

In my terms, this leads to
Vrs(t) = Vs(t) - Vg(t)
= Vs(t) - Vf.g(t) - Vr.g(t)

Your Vg seems to be same as my Vf.g and you seem to be using a
different
sign for Vref than I do for Vr.

You must be carrying these differences through the equations correctly
because the final results seem to agree.

A small aside. It is conventional to use cos for sinusoidal waves
because
it maps more readily into phasor notation.

>   2Vrs(t) = Vs*sin(wt + 90) + Vs*sin(wt)

>
> In summary, power to the resistor Rs comes via two paths, one longer
> than the other by 90 degrees (in this example).

This is not quite complete. The power to Rs does come from two places
but they are the voltage source and the line.

Ps(t) = Prs(t) + Pg(t)

where Pg(t) is the power at point g flowing out of the generator into
the line and Ps(t) is the power flowing from the source to the source
resistor and the line.

The power into the line can be seaparated into a forward component and
a reflected component:

Pg(t) = Pf(t) + Pr(t)

(Sometimes this is written as P = Pf - Pr, but that is just a question
of how the sign is used to represent the direction of energy flow.)

Substituting we have

Ps(t) = Prs(t) + Pf.g(t) + Pr.g(t)
or
Prs = Ps(t) - Pf.g(t) - Pr.g(t)

Whenever Ps(t) equal 0, then Pf.g(t) also equals 0 so at those times,
this simplifies to
Prs = - Pr.g(t)
which is the same conclusion you came to.

But it is wise not to forget the Pf.g(t) term because at times when
Ps(t) is not equal to zero, the Pf.g(t) term will be needed to
balance the energy flows.

> Power flows through both paths to Rs at all times, but because of the
> time differential in arrival timing, at some point Rs will receive power
> only from Vs, and at another point, receive power only from Vref.

And at still other times, the power in the source resistor will depend
on
all of Ps(t), Pf.g(t) and Pr.g(t), or, more simply, it will depend on
Ps(t) and Pg(t).

It would be excellent if you would correct my exposition using the correct formulae. We could then see if your proposal actually provides accurate results.

...Keith

PS. It won't.

The reason for the center being half as high as the ends is that I
have trees on both ends but nothing in the center for support other
than one old short dead tree. Thank you for the insights and
encouragement. I'll begin the attempt to install once the weather
cooperates here in Michigan. WB8YKH

Thanks for looking at my posting very carefully, because I think you are drawing the same conclusions as I, at least so far.

I think you are correct in saying that
> For me, Vg(t) is the actual voltage at point Vg. In terms of forward
> and
> reverse: Vg(t) = Vf.g(t) = Vr.g(t), meaning the actual voltage at
> point
> g is sum of the forward and reverse voltage at point g.
>
but doesn't this describe the standing wave?

At point g, the forward wave has passed through resistor Rs, loosing part of the original wave energy, and is inroute beginning the long path to the resistor Rs. The reflected wave has arrived back to one side of Rs and the voltage is already in series with the source voltage acting on Rs. I think we need to subtract the two terms so that we can separate the apples and oranges.

This is an important observation. cos(0) is 1 so to me it seems like we are saying that we begin at time zero with peak voltage or peak current. I wanted to begin with zero current at time zero so I used the sine. Am I missing something important here?

No, I think my Pr.g(t) was positive, not negative. The difference is important because of the timing of the energy flows. Here is where it is important to observe that the forward wave entering the transmission line will have no further effect on resistor Rs until it has traveled 90 degrees of time. On the other hand, the reflected wave Pr.g(t) is only an instant of time away from entering the resistor Rs, but has not actually entered it because you are measuring it as being present at Vg, not as voltage Vrs.

>
> But it is wise not to forget the Pf.g(t) term because at times when

Pf.g(t) is the remaining power after the wave generated by Ps(t) has passed through Rs and left behind Prs(t). Another Prs(t + x) will be generated by the returning reflected wave.

We differ on how to utilize the term Pg(t). I think it describes the standing wave, not the voltage across Rs.

Just an idea, how about a end fed zep?

Gain should be the same without the mechanical problem of trying to feed
the antenna in the center.

You should be able to get it a little higher in the middle. Enough
tension on the ends and you could have maybe 10 feet of droop instead of 20.

Another option I've seen used is to use a messenger rope that runs the
entire length of the antenna. With a sturdy rope, you can relieve the
tension on the antenna wires by having the tension on the rope

Your idea to use an end fed zep sounds interesting however I am
attempting to raise a double bazooka coaxial dipole I purchased at the
Dayton Hamvention two years ago. WB8YKH

>
> Sources is not grounded.

Yes, unfortunately noise that is generated more than one or two wavelengths away from your antenna will be almost entirely electromagnetic by the time it reaches your antenna. Antennas do not differentiate between "electrically generated" and "magnetically generated" noise, when you are far enough that the electromagnetic field dominates over any near-field electric or magnetic field. The balanced small loop is good for rejecting electric-field noise only if (1) the noise is generated close to the antenna and (2) the antenna is close to the ground (so the electric field is guaranteed to be nearly vertical) -- -- where "close" means relative to a wavelength. So the small balanced loop is especially good for LF and VLF work.

Perhaps someone else will have suggestions about what else you might try.

Cheers,
Tom

>
>I'd never heard of a messenger rope. Sounds interesting. How is the
>messenger rope secured to the antenna line? WB8YKH

More properly "messenger line".

This seems to be a difficult item to search so I will attempt to an
explanation...

When two ships meet at sea and wish to transfer items from one ship to
another (think mail, movies, etc.) they must keep a safe distance
between them. The accepted procedure is to throw or otherwise launch a
small rope or line from one to the other. Then a larger line is
attached to the small line and pulled back to the originating ship.
There may be several iterations of this until a line strong enough to
carry the ultimate load is in place. The first line (and may be the
interim lines) that were used to get the final line in place are
refferred to as messenger lines.

I sometimes use a weighted piece of fishing line as the meesenger and
tie the string/rope/wire in place to hang an antenna. It saves a lot
of snagging if you streamline the attaching knot with a bit of tape.

If anyone manages to figure out a search that provides useful results
for "messenger line" I would appreciate the enlightenment!

John Ferrell W8CCW
Beware of the dopeler effect (pronounced dope-ler).
That's where bad ideas seem good if they come at you
fast enough.

Keith Dysart wrote:
> But you need to clearly state your limitations and stop
> flip flopping.

What you are calling "flip flopping" is me correcting
my errors. Once I correct an error, I don't flip-flop
back. My error was in assuming that the power-density
(irradiance) equation only works on average powers.
K7ITM convinced me that it works on instantaneous powers
also.

> I am surprised, this being 2008, that I could actually be
> offering a new way to study the question, but if you insist,
> I accept the accolade.

I'm sure you are not the first, just the first to think
there is anything valid to be learned by considering
instantaneous power to be important. Everyone except
you discarded that notion a long time ago.

> Analysis has shown that when examined with fine granularity,
> that for the circuit of Fig 1-1, the energy in the reflected
> wave is not always dissipated in the source resistor.

Yes, yes, yes, now you are starting to get it. When
interference is present, the energy in the reflected
wave is NOT dissipated in the source resistor. Those
facts will be covered in Part 2 & 3 of my web article.

>> Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(A)

>
> Ps(t) = Prs(t) + Pg(t)
> or
> Pg(t) = Pf.g(t) + Pr.g(t)
>
> In fact neither do.

For instantaneous values of voltage, the phase angle is
either 0 or 180 degrees so the cosine term is either +1
or -1. The math is perfectly consistent. That you don't
recognize the sign of the instantaneous interference term
as the cosine of 0 or 180 is amazing.

> Non-the-less do feel free to offer corrected expression that include
> the 'cos(A)' term.

I did and you ignored it. There is no negative sign in the
power equation yet you come up with negative signs. That
you don't recognize your negative sign as cos(180) is
unbelievable.

> The math holds as it is. But I invite you to offer an alternative
> analysis that includes cos(A) terms. We can see how it holds up.

It it unfortunate that you don't comprehend that the cos(0) is
+1 and the cos(180) is -1. The sign of the instantaneous
interference term is the cosine term. The math certainly does
hold as it is - you are just ignorant of the "is" part.

How about expanding those equations for us?

Vs(t) = 141.4*cos(wt) ????
Vg(t) = ____*cos(wt+/-____) ????
Vf.g(t) = ____*cos(wt+/-____) ????
Vr.g(t) = ____*cos(wt+/-____) ????

If you ever did this before, I missed it.

Given the correct voltage equations, I can
prove what I am saying about destructive and
constructive interference averaging out to zero
over one cycle is a fact.

No, I really don't.

I do understand that you had better not try to find the power flowing from superposed voltages because they may be the sum of apples and oranges. That is, the superposed voltages may be flowing in opposite directions so they will each be carrying power but the power will be available/reachable only for the direction toward which the wave is traveling. An SWR meter comes to mind here.

John while what you describe is correct, it is not the type of messanger
rope, line, or cable that is being thought of.

In the antenna case, it is a strong rope that is streached between two
supports. To this rope is attached a lighter antenna. Say you only have
some number 20 wire and want to make an 80 meter dipole. If you string the
20 wire and attach some rg-8 type coax to the middle of it, it would
probalby not stay up very long. Also you would have to have a large drop in
the middle as you can not streachit very tight without breaking.
If you have a strong rope you can tape and use some ultraviolet resistant
wire ties to attach the antenna wire to the rope and then pull it up
tighter.

I have a tower up 60 feet with several beams on it. While it may not be the recommended practice, I came off the tower around the 40 foot level and ran the coax (4 coax +rotor cable) to the house about 50 feet away. I used a piece of guy wire and taped and ty wrapped the cable to the the guy wire. I pulled this guy wire tight enough to keep the cable off the ground. This particular guy wire is not one of the supporting guys, but just a 'messanger wire' to hold up the coax with out strssing the coax.

You might do a bit of research on the equipment that various animal tracking organizations use. They tend to use the 215 - 218 MHz band for tracking various animal species, and the equipment should suit your needs also.

Maybe the center tree could support a taller support pole for the
bazooka.

It is because (V1 + V2)^2 usually doesn't equal V1^2+V2^2
because of interference. Keith's addition of powers
without taking interference into account is exactly
the mistake that the EE201 professors were talking about.
One cannot validly just willy-nilly add powers. It is
an ignorant/sophomoric thing to do.

If we add two one watt coherent waves, do we get a two
watt wave? Only in a very special case. For the great
majority of cases, we do *NOT* get a two watt wave. In
fact, the resultant wave can be anywhere between zero
watts and four watts. The concepts behind Keith's
calculations are invalid. If you are also trying to
willy-nilly add powers associated with coherent waves,
your calculations are also invalid.

OK, yes, I agree. It is OK to add powers when you are adding the power used by light bulbs. It is not OK to willy nilly multiply the voltage or current by the number of bulbs to learn the power used. You must carefully consider the circuit that connects the bulbs before selecting the proper method of calculating power, especially the possibility that the bulbs may be connected to phased power as in 3 phase or in traveling waves.

I've also seen "messenger line" or more often "messenger wire" used to
describe the steel wire that supports such things as telephone cables
between poles and mains power service drops from the pole to a building.

I got a bunch of free 75 ohm coax from the TV cable
company that has a messenger wire. It seems to me to
be for strain relief to keep the coax from breaking
from wind or ice.

OK, I got it!
I usually use Nylon line (home improvement store, about 150 pound
test) for that purpose. You can sure do a lot of experimenting for
very little money that way.

Antennas can be a lot of fun....

Rumor has it that this antenna will be in the next ARRL Antenna
Handbook. Our club had an antenna party here recently where we built a
bunch of these. I chose to not glue mine together so it will store in
a very small package. You can also leave off elements at will to
reduce the physical size if needed.

Unfortunately, recent knee replacement has left me sidelined for a
while.

That is a very worthwhile objective. All that noise adds to the
intermod noise and the sooner you can stop it, the better.

In my youth I recall calling CQ on 42 mhz for a couple of weeks.
Fortunately, a very sharp yagi and very low power saved me from a
violation.

Since the roof of a house is fairly large, a more conventional random
length loop tuned with something like a LDG or SGC autotuner at the
feedpoint might be a good approach. Icom IC-AH4 could probably also work.

>
> I wonder what the size and cost of the Vacuum variable is to make a

size of a pickle jar
Several hundred dollars, depending on size, power handling, and source..

http://www.surplussales.com/VaccumVarCaps/VVC5.html
http://www.mgs4u.com/RF-Microwave/vacuum-variable-capacitors-500.htm

plus you'll need to cobble up a motor and drive system.

the $300 or so for a autotuner starts to look like a good deal.

Actually, at 150W, it might not be using a vacuum variable, just a
suitable air variable with big spacing. Electrically, this is much the
same as the AEA isoloop or MFJ-1782 type antenna. The ARRL antenna book
has a whole chapter on them, generically.

Ooooppps. That should have been Vg(t) = Vf.g(t) + Vr.g(t)

> but doesn't this describe the standing wave?

Not by itself. It is simply the function describing the voltage at
point g.

If you were to compute Vx(g) = Vf.x(t) + Vr.x(t) for many points
x, then you might end up with something akin to a standing wave.
Note that Vg(t) = Vf.g(t) + Vr.g(t) holds true for any function
while standing waves only really appear when the excitation
function is sinusoidal.

> At point g, the forward wave has passed through resistor Rs,

This is not a way that I would recommend thinking about what is
happening. The voltage source and source resistor are lumped
circuit elements and thinking that wave is passing through
them is likely to lead to confusion.

It might be valuable to study the circuit completely with a
lumped voltage source, source resistor and reactance. Once
that circuit is understood, replace the reactance with the
transmission line. When studying the circuit with the
transmission line instead of the reactance, always check
to see whether you would use the same words if the TL were
replaced with the reactance. If not, question why.

> loosing part of the original wave energy, and is inroute beginning the long path to the resistor Rs. The reflected wave has arrived back to one side of Rs and the voltage is already in series with the source voltage acting on Rs. I think we need to subtract the two terms so that we can separate the apples and oranges.

It does not alter the outcome, so is not that important.

I think that is just because your reference direction was different.
I use the same reference direction for both Pf and Pr. It is often
done that the reference direction is different for Pf and Pr.

> The difference is important because of the timing of the energy flows. Here is where it is important to observe that the forward wave entering the transmission line will have no further effect on resistor Rs until it has traveled 90 degrees of time. On the other hand, the reflected wave Pr.g(t) is only an instant of time away from entering the resistor Rs, but has not actually entered it because you are measuring it as being present at Vg, not as voltage Vrs.

> We differ on how to utilize the term Pg(t). I think it describes the standing wave, not the voltage across Rs.

I describe Vg(t) as the actual voltage that would be measured by an
oscilloscope at the point g; i.e. the beginning of the transmission
line. It is certainly not the voltage across Rs. Perhaps it IS what
you mean by standing wave. In any case the voltage across the resistor
is
Vs(t) = Vrs(t) + Vg(t)
Vrs(t) = Vs(t) - Vg(t)

Pg(t) is the power being delivered to the transmission line at any
instance t.
Pg(t) = Vg(t) * Ig(t)

Actually the flip-flopping I was referring to was the
constant changes in your view of the limitations that
apply to your claim.

Is this a flop or a flip? Are you now agreeing that the
energy in the reflected wave is only dissipated in the
source resistor for those instances when Vs is 0?

I could not find them in the archive. Could you kindly provide
them again, showing where the 'cos(A)' term fits in the
equations:
Ps(t) = Prs(t) + Pg(t)
and
Pg(t) = Pf.g(t) + Pr.g(t)

> There is no negative sign in the
> power equation yet you come up with negative signs.
[gratuitous insult snipped]

Negative signs also arise when one rearranges equations.

I did. And they are also conveniently in the spreadsheet at
http://keith.dysart.googlepages.com/generator,line,load,reflection

For your convenience, in the example of Fig 1-1, 100 Vrms
sinusoidal source, 50 ohm source resistor, 45 degrees of
50 ohm line, 12.5 ohm load, after the reflection returns...

Vs(t) = 141.42135623731*cos(wt)
Vg(t) = 82.46211251*cos(wt+30.96375653)
Vf.g(t) = 70.71067812*cos(wt)
Vr.g(t) = 42.42640687*cos(wt+90)

And for completeness...

Ps(t) = 100 + 116.6190379cos(2wt-30.96375653)
Prs(t) = 68 + 68cos(2wt-61.92751306)
Pg(t) = 32 + 68cos(2wt)
Pf.g(t) = 50 + 50cos(2wt)
Pr.g(t) = -18 + 18cos(2wt)

Since I am not sure exactly what your are looking for,
and you could not be sure that I did them right,
it would probably be best if you were to compute these
equations which you need.

> OK, yes, I agree. It is OK to add powers when you are adding the power used by light bulbs. It is not OK to willy nilly multiply the voltage or current by the number of bulbs to learn the power used. You must carefully consider the circuit that connects the bulbs before selecting the proper method of calculating power, especially the possibility that the bulbs may be connected to phased power as in 3 phase or in traveling waves.

My analysis used voltages, currents and impedances to compute
all the voltages and currents within the circuit. Some were
derived using superposition of voltages and currents but most
were derived using basic circuit theory (E=IR, Ztot=Z1+Z2, etc.)

Having done that, the powers for the three components (the
voltage source, resistor, and entrance to the transmission line)
in the circuit were computed. These powers were not derived using
superposition but by multiplying the current through the component

by the voltage across it. This is universally accepted as a valid operation.

Having the power functions for each of the component, we can then turn to the conservation of energy principle: The energy in a closed system is conserved.

This is the basis for the equation
Ps(t) = Prs(t) + Pg(t)
This equation says that for the system under consideration (Fig 1-1), the energy delivered by the source is equal to the energy dissipated in the resistor plus the energy delivered to the line. This is extremely basic and satisfies the conservation of energy principle. This is not superposition and any inclusion of cos(theta) terms would be incorrect.

The equation
Pg(t) = Pf.g(t) + Pr.g(t)
is more interesting. The basis for this is superposition. The forward and reverse voltage and current are superposed to derive the actual voltage and current. It would seem invalid to also sum the powers. To me it was a complete surprise that summing the voltages produces the correct total voltages and, at the same time, summing the powers (which are a squared function of the voltage) also produce the correct result.

But by starting with the equations used to derive forward and reverse voltage and current, it can be easily shown with appropriate substitution that Ptot is always equal to Pforward + Preverse (Or Pf - Pr if you use the other convention for the direction of the energy flow)s. It simply falls out from the way that Vf and Vr are derived from Vactual and Iactual.

So
Pg(t) = Pf.g(t) + Pr.g(t)
is always true. For any arbitrary waveforms. Inclusion of cos(theta) terms would be incorrect.

It only holds true when Z0 is purely real. Of course, when it isn't, time domain analysis becomes very much more cumbersome. But it's not hard to show the problem using steady state sinusoidal analysis, and that's where the cos term appears and is appropriate.

I hadn't associated it with the DDRR antenna. I am familiar with it a
little. Is this a variation of that?

I recognize that any small, and most stealth antennas will be
compromise antennas, but then, isn't any antenna a compromise to some
degree.

That is certainly an idea I hadn't thought of. It sounds cheaper and
easier to build. The same concept could be used with raising and
lowering the antenna, but instead of a 'loop', it could be a wire.

Thought: let's assume one puts up a loop on the roof. The ground side
is a single wire running over the peak of the house roof, folds up at
90 degrees for 3-6 feet, back across the roof 6 foot above the peak
and back down to the hot lead of the autotuner. Would that not
circumvent the need for the capacitor at the far end? and would the
loop have to be trimmed to a particular size to operate the various
bands, or could the tuner actually operate with most any size loop.

Disclaimer: I know from experience that some random lengths might not
work on all bands, but some do appear to. I recognize that there
could be inefficiencies...

This is what I was fishing for. Maybe the antenna design isn't the best, but the discussion is introducing variations of thinking that could be useful.

Thank you
Buck

My first thoughts are that instead of a 75 ohm antenna, you will now
have one closer to 50 ohms. It may have an unnoticeable loss figure
due to the shortened length between the ends of the antenna, and if
you tune it to a higher frequency (tune, not trimmed in length) you
may find it more of NVIS, for example, a 40 meter v-pole might be
almost equivalent to a dipole, but on 15 meters, it would point strait
up.

Question: can you pull the legs through an insulator or something so
you have hanging legs instead of a drooping center?

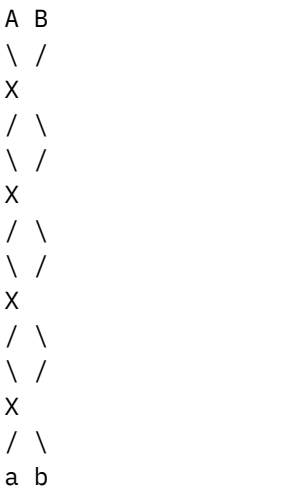
3500. Wrapped Antenna Feeding

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-22 09:46:51 UTC
From: Buck <usenet01@lumpuckeroo.com>
Message-ID: <j9k9u3ptl65h0mjujjlr0641gld26ol7at@4ax.com>
Source record: 26822



The above diagram represents a piece of material with two wires wrapped around it. One is wrapped clockwise and the other is counter clockwise. The first wire is a to A and the second is b to B.

For the sake of discussion I am going to assume the piece of material is a 1" diameter pvc pipe and the wire lengths are each 16 feet or the equivalent of a 1/4 wave for 20 meters.

I realize that the inductance will create a variation, but since this is hypothetical, I am assuming this is a 20 meter antenna. Also assume it is 20 feet or more above the ground with no ground plane radials.

There are several scenarios for feeding this antenna. My question is what kind of performance could I expect by each of the variations below?

1) Feed ab - This is like a dipole with the elements intertwined.

2) Short AB and feed ab - a closed loop

3) feed Ab - this would require additional wire to reach the ends

4) feed Ab - using bending the pvc like a hula loop.

Thank you

Thanks for providing the limitation.

But I am having difficulty articulating where the math in the
following
derivation fails.

Starting by measuring the actual voltage and current at a single
point on the line, and wishing to derive Vf and Vr we have the
following four equations:

V = Vf + Vr
I = If - Ir

```
Zo = Vf / If
Zo = Vr / Ir

rearranging and substituting
Vf = V - Vr
= V - Zo * Ir
= V - Zo * (If - I)
= V - Zo * (Vf/Zo - I)
= V - Vf + Zo * I
= (V + Zo * I)/2
similarly
Vr = (V - Zo * I)/2

Pf = Vf * If
= Vf**2 / Zo
= ((V + Zo * I)(V + Zo * I)/4)/Zo
= (V**2 + 2(V * Zo * I) + Zo**2 * I**2) / (4 * Zo)

Pr = Vr * Ir
= (V**2 - 2(V * Zo * I) + Zo**2 * I**2) / (4 * Zo)

So, comtemplating that
P = Pf - Pr
and substituting
P = (V**2 + 2(V * Zo * I) + Zo**2 * I**2) / (4 * Zo)
- (V**2 - 2(V * Zo * I) + Zo**2 * I**2) / (4 * Zo)
= 4(V * Zo * I) / (4 * Zo)
= V * I
as required.

So when Zo is real, i.e. can be represented by R, it is
clear that P always equals Pf - Pr. And it does not even
matter which value of R is used for R. It does not have
to be the characteristic impedance of the transmission
line, the subtraction of powers still produces the correct
answer.

But when Zo has a reactive component, it still cancels
out of the equations. So why is this not a proof that
also holds for complex Zo.

I suspect it has to do with complex Zo being a concept
that only works for single frequency sinusoids, but am
having difficulty discovering exactly where it fails.

And if it is related to Zo and single frequency sinusoids,
does that mean that P = Pf - Pr also always works for
single frequency sinusoids?

...Keith

As I said, I corrected an error in my thinking. You
are free to consider that to be a flip-flop, I consider
it to be a step forward.

> Are you now agreeing that the
> energy in the reflected wave is only dissipated in the
> source resistor for those instances when Vs is 0?

Yes, for instantaneous reflected energy exactly as I
previously stated, but not true for average reflected
energy. 100% of the average reflected energy is
dissipated in the source resistor when the transmission
line is 45 degrees long. That intra-cycle interference
exists, thus delaying the dissipation by 90 degrees,
is irrelevant to where the net energy winds up going.

Your conservation of power principle would have you
demanding that the power sourced by a battery charger
must be instantaneously dissipated. Everyone except
you seems to realize that is an invalid concept. The
dissipation of energy can be delayed by a battery
or a reactance. In the present example, the dissipation
of the instantaneous reflected energy is delayed by
90 degrees by the reactance.

> I could not find them in the archive. Could you kindly provide
> them again, showing where the 'cos(A)' term fits in the
> equations:

Go back and read the part where I said cos(0)=+1 and
cos(180)=-1. There is no such thing as conservation of
power. Your equations assume a conservation of power
principle that doesn't exist in reality. The forward
power is positive power. The reflected power is positive
power. The only negative power is destructive interference
which must be offset by an equal magnitude of constructive
interference. When the instantaneous interference power is
negative, the two voltages are 180 degrees out of phase and
that is your cos(180)=-1. When the instantaneous interference
power is positive, the two voltages are in phase and that
is your cos(0)=+1. Why don't you already know all this

elementary stuff?

I suppose that is a name you could use, but do you still
call it "standing wave voltage" when there is no
reflected wave, i.e. Vr is 0 for all time. There is
no standing wave when Vr is always 0.

> Pg(t) = 32 + 68cos(2wt)
> Pf.g(t) = 50 + 50cos(2wt)
> Pr.g(t) = -18 + 18cos(2wt)

Now it is time for you to explain exactly why you
believe in a conservation of power principle. Do
you demand that the instantaneous power delivered
by a battery charger be instantaneously dissipated
in the battery being charged? If not, why do you
require such for the example under discussion?

The correct equation for adding the powers above is?

Prs(t) = Pf.g(t) + Pr.g(t) +/- 2*SQRT[Pf.g(t)*Pr.g(t)]

The last term is the interference term. The sign of
the interference term is negative if Vf.g(t) and
Vr.g(t) are out of phase. The sign of the interference
term is positive if Vf.g(t) and Vr.g(t) are in phase.
Vf.g(t) and Vr.g(t) are in phase for half of the cycle.
Vf.g(t) and Vr.g(t) are out of phase for the other half
of the cycle. The "excess" energy from the destructive
interference is dissipated in the source resistor as
constructive interference after being delayed by 90
degrees.

Hello Buck,

Assuming real world materials are used:

Both AB, ab (situations 1 and 2) whether shorted or not will be a very, very bad radiator (you made a twisted pair as distance between wires << Wave Length). It is an electrically small structure; you don't get end-fire (upwards) radiation.

Your situation 3 depends on the routing of the return wire, so this one cannot be answered

Situation 4 will radiate as a loop (assuming symmetrical feed so that feed line does not contribute to radiation).

Best will be connect ab and feed over ground or counterpoise (running horizontally or downwards).

Best regards,

Wim

Why is that a surprise to you? I have been telling you
for many days about that special case where:

(V1^2 + V2^2) = (V1 + V2)^2 for zero interference

This applies equally well to phasors or instantaneous
values of voltage. The above special case is what my
Part 1 article is all about.

Since a 45 degree long transmission line forces the
above RMS voltage equation to be true for all values of
resistive loads, the *average* reflected power based on
RMS voltage values is *always* dissipated in the source
resistor. Since a conservation of power principle does
not exist, it is perfectly acceptable for destructive
interference energy to be stored for part of the cycle
and be dissipated later in the cycle.

> So
> Pg(t) = Pf.g(t) + Pr.g(t)
> is always true.

Of course it is true but it says absolutely nothing about
the dissipation of the reflected power in the source resistor
which is the subject of the discussion. The above equation
remains always true while the dissipation of the reflected
power in the source resistor varies from 0% to 100%.

We are not discussing matched systems. If the total
RMS voltage differs from the RMS forward voltage,
then Vr is NOT zero.

I am very impressed with this series of equations/relationships. These equations clarify your previous postings and provide a basis for future enrichment.

I think that a complex Zo would not be a transmission line, but would be an end point. Any complex end point could be represented by a length of transmission line with a resistive termination. Once that substitution was made, the problem should come back to the basic equations you presented here.

If you have horizontal room, you can do somewhat better. Put insulators on the ends, and pull out the ends so they go down at 45 degrees, or something, rather than hanging straight down. I am doing this on a 75 meter dipole that is supported by two 80 foot trees that are 60 feet apart. The antenna looks somethging like an upside down W.

:-) Oh, no, not photons again! When you are near to a source -- to a
transmitting antenna or to a computer radiating noise -- the fields in
general have not developed fully into electromagnetic waves -- photons
if you wish. It is quite usual that, close to the source, either the
electric or the magnetic field will dominate. Often from noise
sources, the near field is predominantly electric, and a properly done
loop antenna will reject that, responding only to the, um, photons.

There is a hint here: it is common that tall buildings incorporate a
lot of steel, and that will likely act as a shield. I hope this
antenna is not mounted inside!

A reasonable thing to do, though a good receiver with a low-distortion and fairly narrow-band front end should not have trouble with out-of-band signals (noise). Do you have a quantitative measure of just how strong this out of band noise is? I'd personally much rather use a preselection filter separate from the antenna, and close to my operating position, to reject out-of-band signals. Even though the antenna you have described has very high Q, I believe I could do better with a two or three resonator filter running at lower Q, since the slope of the attenuation versus frequency is much greater. Unless there was some especially strong signal in the band, I would at least consider a fixed-tuned bandpass filter that covered my band of interest, assuming that band is fairly narrow such as 7.0-7.1MHz.

Can you tell that you are getting the expected antenna bandwidth, about 3kHz at the 3dB points at 7MHz?

If the amplifier at the antenna has a tendency to oscillate, it very likely also has poor intermodulation performance. Be careful that it doesn't destroy the benefits you are trying to obtain.

Cheers,
Tom

Thanks Kingfish. That's pretty cool! It's actually much like what we're
using now... A 4 element Yagi, though ours don't have the flexible elements
like one made of tape measure.

Thanks ARMYbrat. This USMCbrat appreciates it, and everything else! :)

Most of what I've found thus far is about the same as what we're currently using, which is a flat 4 element Yagi. I may not be versed enough to describe the plans I'm looking for, but when I find them I'll post here.

The antenna I'm looking for is perhaps better described as a 4 element Box or Cube Yagi where the frame is built of 1/2 inch PCV and the elements are fairly heavy guage wire. There's no sharp points to hurt someone's eye, which is frowned upon by the California Highway Patrol for use in their helicopters. There's a guy that I trained with who has the plans and hasn't yet gotten back to me with them, but I'll be persistent and let people here know when I get the plans.

Thanks Ed. That's a good idea, and you're exactly right... what we're doing looks just like what you'd see on a television nature show where someone had a radio collar on a lion or something like that. We're applying the same technology to Alzheimer's patients who are at risk of wandering.

[several references to]
... "messenger line"...

Hotwire fencing. The stuff that we put around horse
pastures. For intended use, it connects to a hi volt,
low current, pulsed source.

There is a version of the 'wire' that is very fine gauge wire,
perhaps 28 ga or smaller, woven into nylon webbing.
You can tie it in knots, put a lot of tension
on it, without bothering the conductor.

Built in messenger line with the element.

Prs(t) = Pf.g(t) + Pr.g(t) +/- 2*SQRT[Pf.g(t)*Pr.g(t)]

= [SQRT(pf.g(t) + SQRT(pr.g(t)]^2

and/or= [SQRT(pf.g(t) - SQRT(pr.g(t)]^2

How can we justify calling the +/- 2*SQRT[Pf.g(t)*Pr.g(t) term the "interference term"?

Am I correct in assuming that this equation describes the instantaneous power delivered to Rs?

Search Google with "cubical quad" and you'll find what you want, I think.
There are even some calculators for this type antenna listed.

http://en.wikipedia.org/wiki/Quad_antenna

N4PGW and WB2TT - Your responses were very interesting to me and
certainly worth my try. Yes, with my low center feed on the bazooka
coax dipole I can drop the ends to form an "M" shape. Do you know how
the radiation pattern would be effected? WB8YKH

I haven't tried it with the ends hanging straight down, but mine is the same
length as a regular dipole. EZNEC plot looks like a dipoles.

Tam

You're welcome. You might also consider some of the new GPS
products.... often made for tracking cars... but some small enough to place
on a person. You could sit at the comfort of a computer and track them!

Ed :^)

> in the battery being charged?

Are you making this a trick question by using the
word "dissipated"?

If not, then yes. Consider my laptop which has an
external power supply connected by a cord to the
laptop.

Conservation of energy means that the instantaneous
energy flow (i.e. power) along this cord into the
laptop is always exactly equal to the sum of
- the sum of energy being dissipated as heat
in each individual component
- the increase in energy being stored in
components such as capacitors, inductors
and batteries, minus any stored energy
being returned from components such as
capacitors, inductors and batteries
- energy being emitted such as
- light (e.g. display)
- sound (e.g. fans, speakers)
- RF (e.g. Wifi antennas, RFI)
- etc.

So yes, the phrase "conservation of power" is
appropriately descriptive and follows from
conservation of energy.

> If not, why do you
> require such for the example under discussion?

I require it for both.

> of the cycle. The "excess" energy from the destructive
> interference is dissipated in the source resistor as
> constructive interference after being delayed by 90
> degrees.

Where is "cos(theta)" in this?
And what "theta" is to be used?
Is it the same theta that was used to conclude that
this was a "no interference" example?
See "A Simple Voltage Source - No Interference" at
http://www.w5dxp.com/intfr.htm

So the plus/minus in the equation aboves means that
for part of the cycle we should add and part of the
cycle we should subtract.
This equation is ambiguous and is therefore incomplete
since it does not tell us when we should add and when
we should subtract.
Could you provide a mathematically precise description
of when we should do each?

Where is this destructive interference energy stored
while waiting to be dissipated constructively later?
If it is in a capacitance, which one? Does the
voltage on the capacitance increase appropriately
to account for the energy being stored?
Similarly if it is stored in an inductance.

...Keith

True for this example. But it is generally unwise to pick
names or descriptions that will have to change when
the component values are changed.

> I think that a complex Zo would not be a transmission line, but would be an end point.
 Any complex end point could be represented by a length of transmission line with a
resistive termination. Once that substitution was made, the problem should come back to
the basic equations you presented here.

The characteristic impedance for a transmission line is
Zo = sqrt((R + jwL) / (G + jwC))

For a lossline (no resistance in the conductors, and no
conductance between the conductors), this simplifies to
Zo = sqrt(L / C)

So real lines actually have complex impedances. But the
math is simpler for ideal (lossless) lines and there is
much to be learned from studying the simplified examples.

But caution is needed when taking these results to
the real world of lines with loss.

Yes, I concur with these comments.

The characteristic impedance can also be found from

Zo = 1/(C*Vel)

where C is the capacitance of the line per unit distance and Vel is the velocity of the wave.

This second solution for Zo demonstrates the power storage capabilities of the transmission line over time.

But as you say, real lines also have resistance losses and other losses so use great care when taking these results into the real world

I have up a half size G5RV and want to add 80 metres it. I don't have the space for a full size.

What is best to go for a 80m inductor kit or a pair of 80m traps?

Thanks

well, 'traps' are usually used to cut off an antenna that is too long for
the band in question, so that is probably not what you want. simple
inductors are used to make an antenna look longer so that is what you would
want... but expect it to affect tuning on all bands, not just add 80m
capability.

Do a Google search on 'G5RV+extend'.
There seems to be a lot of information available.

"making" them is easy, just wind some wire around some kind of form, like a piece of pvc pipe. figuring out how much wire, how many turns, and the diameter is the hard part. I would use one of the antenna modeling programs to figure that out given your current design and picking a point where you think you can insert them. from that you could get a value of inductance needed, then pick a likely form size and use one of the inductance calculators on line to figure out how many turns of wire it would take.

"Is it hard to make a pair of inductors and how would I go about
making a pair?"

It's a coil. So, make a couple of coils of wire, typically on a form
of some kind cuz just wire tends to unravel if not held together some
way. That form ought to be non-conductive, PVC pipe for instance.
'Fatter' coils tend to be shorter than 'skinny' coils, and more
efficient sort of (to some ridiculous point), take up less room. How
long/diameter? Beats me. Make them what you think is too big and
then try shorting out turns of each coil till you get to where you
wanna go. That'll work for one band, probably not too well for two
bands, ain't gonna work for all bands at one time unless you make
those coils adjustable (coil taps).
Expect compromises. Won't be the 'best' in the world, but it'll work.

I will have a look for a antenna modelling program that I can get on with.
Also I'm using pvc covered flexweave wire for my G5RV. Is it all right to
make the inductors up from flexweave or should I get some enamelled copper
wire, or doesn't it really matters?

Thanks

Page 388, "Optics", by Eugene Hecht, 4th edition:
"The interference term becomes I12 = 2*SQRT(I1*I2)cos(A)"
where 'I' is the Irradiance (power density)[NOT Current]
Later Hecht says +2*SQRT(I1*I2) is the total constructive
interference term and -2*SQRT(I1*I2) is the total
destructive interference term. Chapter 9 is titled
"Interference" - recommended reading.

> Am I correct in assuming that this equation describes the instantaneous power delivered to Rs?

Yes, if Tom, K7ITM, is correct about the equation working
for instantaneous power densities, not just for average
power densities as I had first assumed.

Let's say the instantaneous forward voltage dropped across
the source resistor is +50 volts and the instantaneous
reflected voltage across the source resistor is -30 volts.
The source resistor is 50 ohms.
Pf.rs(t) = (+50v)^2/50 = 50w
Pr.rs(t) = (-30v)^2/50 = 18w
Prs(t) = Pf.rs(t) + Pr.rs(t) - interference
Prs(t) = 50w + 18w - 2*SQRT(50*18) = 8 watts

If Tom is correct, that should be the actual dissipation
in the source resistor at that time which includes 60 watts
of destructive interference that will be dissipated 90 degrees
later when 2*SQRT(50*18) = +60 watts.

Keith Dysart wrote:
> So yes, the phrase "conservation of power" is
> appropriately descriptive and follows from
> conservation of energy.

You have a contradiction built into your concepts.
You have argued that the instantaneous power dissipated
in the source resistor is not equal to the instantaneous
forward power component plus the instantaneous reflected
power because power must be conserved at each instant of
time. That is simply not true.

I'm telling that energy must be conserved at each instant
of time but power does not have to be conserved at each
instant of time. Energy can obviously be stored in a
battery or network reactance for dissipation later in
time.

Do you require that the power used to charge a battery
be instantaneously dissipated in the battery? Of course
not! That's true for a dummy load but NOT for a battery.
There is no reason to require dissipation of power at
each instant of time to balance. Since energy can be
stored, there is no such thing as conservation of
instantaneous power, only of instantaneous energy.

> Where is "cos(theta)" in this?
> And what "theta" is to be used?

How many times do I have to explain this? For instantaneous
values of voltage, if the sign of the two interfering voltages
are the same, theta is zero degrees and the cosine of theta is
+1.0. If the sign of the two interfering voltages are opposite,
theta is 180 degrees and the cosine of theta is -1.0.

> Is it the same theta that was used to conclude that
> this was a "no interference" example?
> See "A Simple Voltage Source - No Interference" at
> http://www.w5dxp.com/intfr.htm

That theta is the phase angle of the phasor. If you
would switch over to phasor notation for your values
of instantaneous voltages, it might make things clearer
for you. You have been dealing only with real part of
the phasors which limits theta to either zero or 180
degrees.

> So the plus/minus in the equation aboves means that
> for part of the cycle we should add and part of the
> cycle we should subtract.
> This equation is ambiguous and is therefore incomplete
> since it does not tell us when we should add and when
> we should subtract.

I have told you about five times now. If the sign of the two interfering voltages are the same, the interference term has a positive sign (constructive). If the sign of the two interfering voltages are opposite, the interference term has a negative sign (destructive). Instead of me having to keep posting this over and over how about you keep reading it over and over until you understand it?

> Could you provide a mathematically precise description
> of when we should do each?

See above. If we deal with phasors, theta is the phase angle between the two interfering voltages. If we deal only with real values, theta is limited to either zero (cosine = +1.0) or 180 degrees (cosine = -1.0).

> Where is this destructive interference energy stored
> while waiting to be dissipated constructively later?

In our 45 degree shorted stub example, it is stored in the equivalent inductive reactance of the stub. For each instant in which destructive interference energy is stored, there is an instant in time 90 degrees later when that same energy is dissipated as constructive interference power in the source resistor. That's why 100% of the average reflected power is dissipated in the source resistor for these special cases of zero average interference.

Thanks for your thoughtful reply.

TanH(30/50) = 30.96 degrees. This takes us back to the 12.5 ohm load example.

Is it possible that in your example here, the reflected voltage acts in series with Rs but arrives 90 degrees out of phase with the forward voltage? If so, then

Vrs = sqrt(50^2 + 30^2) (the reflected voltage should ADD to the source voltage)

= sqrt(3400) = 58.31v

The power to Rs would be

Prs = (V^2)/50 = 3400/50 = 68w

We previously found that 32w was used at the 12.5 ohm load, so 32 + 68 = 100w. The entire output from the source is accounted for.

If this is the case, we have here an example of constructive interference, and complete accounting for the power.

You might wonder why I would consider this alternative. If the destructive interference included a 90 degree delay, how would I know whether the 30v was the delayed voltage or exactly in phase with the source? It must be delayed by 90 degrees because the forward voltage is always 90 degrees ahead of the reflected wave (in 45 degree line length example).

Your example certainly works as written, but it also introduces a dilemma. Where is the power stored for 90 degrees?

To answer that question, I see two possiblities: The source voltage causes a reflection so the 60w is stored as an additional reflected wave on the transmission line.

Or second, the 60w is stored in the source.

whatever you can wind with. solid copper will stay in place better by
itself being a bit springy, flexweave you would probably have to glue down
to the form to keep it from sliding around.

What is old is new again.

Hasn't this "formula" been put in the ground once before? For one,
what is velocity but something that has to be computed first only to
find us refilling all the terms back into this shortcut? For two,
"power storage capabilities... over time?" Apparently the stake
missed the heart of this one.

If you would like to build air inductors very similar to B&W AirDux
coils, I highly suggest you go to: http://www.qsl.net/n1lo/antenna.htm
and download the instructional PDF found at the bottom of that page titled
"80-10M mobile vertical." It includes excellent instructions and parts
locations to do this.

If you add inductors to a G5RV, it will no longer be a G5RV. You might be
better off with an 80 - 10 m trap dipole. It will be shortert than an 80
meter dipole.

Tam/WB2TT

3543. Double dipole better than YAGI 5 elements??

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-23 18:56:27 UTC
From: user <dag@allemaale.be>
Message-ID: <fs694s$r2l$1@registered.motzarella.org>
Source record: 26765

That is what I experienced.

I've constructed this:

Double dipole, vertical polarisation.

```
| | }
| | }lenght=75 cm = 1/4 wavelength
____A____ <--width 1,5 meter = 1/2 wavelength
---------
| |
| |
```

I have a 20Kw tx at 1800meter/2000yard. That gives me probs with
interference. The double dipole is better than the Yagi.

Also directivity is good (all be it I do not have Forward/backward ratio).

I have taken pictures of the 2-dipole and the yagi:
http://users.fulladsl.be/spb13810/loop/yagivs2dipool/

And here how the wiring is done: red and green represent solid copper wires:
http://users.fulladsl.be/spb13810/loop/yagivs2dipool/imag0030edit.jpg

Would it be an idea to use copper tubes?? And would that make the reception
better?? 1/4 inch / 1 cm copper tubing or even smaller??

Thanks !

It's not mounted at all. But for tests I'm put this antenna outside.

Not. Just not received.

I'd personally much rather use a
> preselection filter separate from the antenna, and close to my
> operating position, to reject out-of-band signals. Even though the
> antenna you have described has very high Q, I believe I could do

I will receive QRSS at all. And I think that it would be best way is
using
narrow-band antenna -> filter -> synchronous detector.

> there was some especially strong signal in the band, I would at least

> about 3kHz at the 3dB points at 7MHz?

I'm just testing. I will purchase RF generator in next week and test.
Now I have only self-oscillation frequency.

Antenna looks like working. I'm receiving a lots of Morse signals at
7.000 - 7050 Mhz. But I cant recognize any voice signal.

This is receiving signal. Looks like narrow-band enough. This is not
self oscillation. In self oscillation voltage a few volts.

>(the reflected voltage should ADD to the source voltage)

If you graph the two voltages you will find that half the time
the reflected voltage adds to the source voltage and half the
time the reflected voltage subtracts from the source voltage.
Both are true half the time. You can point out either case on
the graph. That's why the average interference term is zero
for this special case and therefore why 100% of the average
reflected power is dissipated in the source resistor for
this special case.

> You might wonder why I would consider this alternative.
> If the destructive interference included a 90 degree delay,

> exactly in phase with the source?

By looking at the graphs?

> Where is the power stored for 90 degrees?

In the equivalent reactance of the transmission line.

That's what reactances do in AC circuits. They store
energy and deliver it back to the system some time
later.

I just did a quick simulation on EZNEC of your proposed Quad. At 215
mhz the element spacing on the boom is about 1 foot. That means a 4
element yagi or quad should come out to 3 feet long. Similarly, the
element loops will be about 1 foot square.

With no matching attempted 2:1 Swr is easily achieved.

If you are so inclined you could model this antenna with the Demo version of EZNEC. You could also prototype one or more on the kitchen table with masking tape and sticks!

I would think the additional gain of the Quad would make it desirable to drop back to three elements to reduce the size.

Reading through the responses, it seems that your requirement is actually for a shortened wire antenna for 80 and 40.

The starting materials are a half sized G5RV (which is not a G5RV, but one of the many variants).

You could salvage materials from the G5RV to make a trapped 80/40 dipole.

(The traps do not simply work as an on/off switch to disconnect the end sections as implied by some. They might be seen to work that way if they were resonant at the operating frequency, but they need not be, and there is good reason for them to not be resonant at any operating frequency.)

Google around for designs for an 80/40 trapped dipole, there are plenty. Decent articles will include details of the physical construction of the traps.

There is a design on my web site, but it is probably too long for you (we don't know your length requirements other than less than a G5RV, you chose to not share that). Nevertheless, it might be an interesting read, see http://www.vk1od.net/coaxtrap/8040.htm .

These type of antennas are affected by their environment, so you should expect to need to fine tune the configuration. Be wary of varying specific trap designs, you might dig a hole for yourself.

I found a good site on how to make some air spaced coaxial traps for each band but that's all I could find.

Can traps be made up with enamelled copper wire as I have just ordered a real of 20 swg?

I've found some good information on inductors but is there any good sites on making traps with copper wire?

Thanks

Sorry about that, I should of said the length of my garden.
From the bottom of the garden up to the wall of the house it is 60 feet and I do not have any chimney stacks to run wires from. My neighbours are happy with a 20 foot pole at the bottom of the garden. Any higher and there not happy about it so that's it for the height. At least there ok with a 20' pole. I am limited on length of wire and unfortunately the height as well. So any help is welcome.

Unforunately, you have no idea of the situation on the ground here. It is
petty to vote for someone other than Mr. Romney soley since he said that we
do not need the hams. He is quite correct. He never made a disparaging
remark about any hams. The Chronicle interviewer was unable to make any
concrete point to challenge Mr. Romney's assertation.

No. Out of band. I'm now add varicaps and all working! Antenna really
very narrow.

>

It's 7Mhz. quarter wave is 10 miters.

I'm use choking:
between amplifier and antenna
between transformer and coax cable.
For amplifier power wires and gain control.

Hello "user"

Making the elements thicker will increase the bandwidth somewhat, so
it may give better reception at off-center frequencies. It will not
give better performance at the centerfrequency.

I have doubts about whether it will perform better then a good 5
element beam on the center frequency. Did you run some simulations?

Then again at the far end of the wire(s).

>I'm use choking:
>between amplifier and antenna
>between transformer and coax cable.
>For amplifier power wires and gain control.

I've observed that, and I have observed it is not enough from your
photo - if you still have self-oscillation. Your pictures do not
reveal any choking of the RF Out cable.

As for the diagonal arm for "ground." This is fine insofar as it
being placed in the electrical middle of the antenna loop (a ground),
but all this rat's nest of wiring throws the concept of balance out
the window. I see in earlier pictures where you clean that up with
careful routing, but it seems much too busy. This leads me into the
comments following:

On another note, the AGC seems overly elaborate, especially when all
that wire could be introducing the self-oscillation. Further, wiring
in power seems another invitation to problems when a 9V battery would
solve that too. Local power would discard the need for the ground
coming from the loop's perimeter, eliminate unnecessary AGC, reduce
the complexity of choking, lower gain (it obviously has too much), and
give you only one coax coming from the antenna.

You need to solve the self-oscillation through removing complexity.
When you accomplish that, THEN that is the time to add it back in, one
thing at a time. You will probably discover all those features and
design gimmicks are not worth it.

That sounds *exactly* like the one that we used in our training. The guy
who made it said that he used an antenna design calculator on the internet
to come up with the layout. I'm still awaiting plans from him, and in the
meantime I'm interested in seeing if I can do it myself for the technical
exercise.

I'm going to take a look at EZNEC and also google around for "Cubical Quad"
as suggested upthread by John KD5YI. So far this looks like exactly what
I'm looking for.

Thanks!

GPS was discussed in our training, with the main drawback being that if the patient was in a building or under a canopy of trees, etc, there would be no signal.

Again, I would suggest a search of the Google archives in research of
the term "Foxhunting." Antennas with such gain may appear the obvious
choice by graphics of their radiation characteristics, but there are
more matters to location than putting a signal in the peak of a lobe.

I have a friend who has lead many Search and Rescue operation in the
city looking for patients who have "wandered away." Quite frequently
they passed by their quarry (quite closely) simply because of the
urban clutter that presents antennas with these characteristics very
confusing results.

On the other hand, and as many sailors may attest, sharp nulls are
often more compelling location indicators. Such an antenna as the
W8JK with variable phasing can give you both sharp nulls and general
gain (through careful selection of the drive point) on a shorter boom
(and could be designed in the way of a quad).

Yes. But FETs draw more that 10ma each.

> coming from the loop's perimeter, eliminate unnecessary AGC, reduce

Cable length is not problem. I'm living in apartment. I can put
antenna outside the window. But not on the roof.

I can make power supply over coax cable. I can put Atmega8 (en
example) to amplifier and add DACs for operate varicaps, AGC. I can
add rectifier and filter for detect self-oscillation and automatics
reduce AGC. But it's not necessary.

Bzzzzzzzzzzzzt.

> Energy can obviously be stored in a
> battery or network reactance for dissipation later in
> time.

Indeed. And forgetting to include such flows in the summation
would be a serious error.

For example, from the example,
Ps(t) = Prs(t) + Pg(t)
includes Pg(t) which accounts for the energy stored in the
line and later returned. There are no missing flows in
this equation. And Ps(t) also accounts for energy absorbed
in the voltage source. Only the source resistor has a
unidirectional energy flow.

> Do you require that the power used to charge a battery
> be instantaneously dissipated in the battery?

The energy flow into the battery is exactly and always
accounted for by the energy flow that heats the battery
and the energy flow consumed in the reversable chemical
reaction.

The instantaneous flows always sum appropriately to
satisfy conservation of energy. Of course, if one forgets

a flow, then the sum will not balance.

> Of course
> not! That's true for a dummy load but NOT for a battery.
> There is no reason to require dissipation of power at

A strange of way of looking at it. It seems easier just
to say that there is no theta. And add the voltages.

But no matter, I have figured out where your extra term
comes from.

Let us a consider a simple circuit with two voltage sources
(V.s1 and V.s2) in series, connected to a resistor R.

Using superposition we have
V.s1 = R * Ir.s1
and
V.s2 = R * Ir.s2

So
Vr.tot = V.s1 + V.s2
and
Ir.tot = I.s1 + I.s2
This is superposition, and all is well.

The power dissipated in the resistor is
Pr = (Vr.tot)**2 / R
but we could also derive Pr in terms of V.s1 and V.s2
Pr = (V.s1 + V.s2) (V.s1 + V.s2) / R
= ((V.s1)**2 + (V.s2)**2 + (2 * V.s1 * V.s2)) / R
= (V.s1)**2 / R + (V.s2)**2 / R + (2 * V.s1 * V.s2) / R

Now some people attempt to compute a power for each of
the contributing voltages across the resistor and obtain
Pr.s1 = (V.s1)**2 / R

Pr.s2 = (V.s1)**2 / R
When these are added one obtains
Pr.false = (V.s1)**2 / R + (V.s2)**2 / R
which, by comparison with Pr above can easily be seen not to be the power dissipated in the resistor. Pr.false is missing the term ((2 * V.s1 * V.s2) / R) from Pr. It is for this reason that it is said that one can not superpose powers. Simply stated, when powers are dervived from the constituent voltages that are superposed, it is not valid to add the powers together to derive the total power.

Of course for the most part, powers being added are not powers derived from the constituent voltages of a total voltage, so in most cases it is quite valid to add powers and expect them to sum to the total power.

But what do you do if a circuit is superposing two voltages and you are presented with information about the circuit in terms of powers. Well then you can add the powers and include a correction term.

Assume
Pr = Pr.false + Pr.correction
= Pr.s1 + Pr.s2 + Pr.correction
But can we find a Pr.correction? It has to correct for the term missing from Pr.false but present in Pr, i.e. ((2 * V.s1 * V.s2) / R).

Restated in terms of power, ((2 * V.s1 * V.s2) / R) becomes
2 * sqrt(P.s1 * P.s2)
But sqrt has two solutions so we have to write
Pr = Pr.s1 + Pr.s2 +/- 2 * sqrt(P.s1 * P.s2)
which should look very familiar.

As you have correctly pointed out, the sign of Pr.correction is negative when the signs of the constituent voltages are different and positive when they are the same. The reason for this can easily be seen from the derivation of Pr.correction.

This Pr.correction term has nothing to do with interference, it is the correction required when it is desired to add two powers computed from the superposing constituent voltages of an actual total voltage across an element and derive the energy flow into the element.

Note that there is no hint that Pr.correction needs to be stored when it is negative nor come from somewhere when it is positive. It is, after all, just a correction that

needs to be applied when one wants to compute the total power given two powers derived from the constituent voltages of superposition.

Since one needs to know the constituent voltages to determine the sign of Pr.correction, why not just use superposition to compute the total voltage and then derive the power? It would be much simpler. With no need for Pr.correction, interference, storage and release of interference 'energy', ...
(Of course, over in optics land it is difficult to measure the voltage, so suffering the pain of using powers is probably appropriate).

This analysis also makes clear the nature of powers computed from the constituent voltages of superposition. These powers do not represent real energy flows. As discussed far above, real energy flows can be summed to test for conservation of energy. When energy flows do not sum appropriately, then either an energy flow is missing, or one is attempting to sum powers which are not real, for example, having been computed from the constituent voltages of superposition (e.g. Pfor and Pref in a transmission line).

...Keith

I'm afraid the homeland security people would want to talk to you
about that! They tend to get excitied about wires and electronic
equipment near bridges.

But it certainly does have an impressive array of vertical radiators.
It would be quite directional, so hopefully there are some good DX
stations off the ends of this.

I did not use a graph, but created a spreadsheet that calculated Vrs for the short circuit, 45 degree long line. It shows the 90 degree transfer of power that you described. I posted the spreadsheet in PDF format at http://www.fairpoint.net/~rsparks/Reflect_short.pdf.

To me, this shows that my traveling wave analysis on an instant basis is not correct because the energy can not be located precisely on a degree-by-degree scale. Yes, it is correct on the average over 360 degrees, but not instantaneously. We are missing something.

Central to traveling waves is the assumption that the wave is not compressable. The energy is assumed to flow in a consistantly predictable mannor that is linear and described by a sine wave. That assumption is violated when energy is delayed for reasons other than distance of travel, which is demonstrated in this example.

I am not ready to suggest a cure for my traveling wave analysis. I only see that it does not work to my expectations.

Thanks for providing the examples and comments.

Point is, energy can be stored and released at a
later time. You earlier said that reactances do not
store energy for release at a later time yet that
is exactly what reactances do.

> A strange of way of looking at it. It seems easier just
> to say that there is no theta. And add the voltages.

Saying there is no theta is a shortcut that can get
one into trouble as it did with you. Since there is
no such thing as negative energy, there is also no
such thing as negative power. Note there are no
negative power signs in the power density equation
where 'theta' is the phase angle between the two
interfering voltages:

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(theta)

The last term is known as the "interference term",
page 388 of "Optics" by Hecht, 4th edition. When
90 < theta < 180, the sign of the last term is negative
indicating destructive interference. When
0 <= theta < 90, the sign of the last term is positive
indicating constructive interference. When theta = 90,
there is zero interference which is what Part 1 of my
web articles is based upon.

> This Pr.correction term has nothing to do with
> interference, ...

Your argument is not with me but rather is with
Eugene Hecht who defined that term as the "interference
term" in "Optics". Have you even read his chapter on
interference? If not, I would suggest that you do so.
Two other enlightening chapters are on "Superposition"
and "Coherency".

> Note that there is no hint that Pr.correction needs to be
> stored when it is negative nor come from somewhere when
> it is positive.

You're correct, there's no hint. It is spelled out in
detail in "Optics". The possibilities are listed below.

Your above statement is a conceptual violation of the
conservation of energy principle. In the absence of
any other energy source or energy sink, localized
destructive interference must exactly match the
localized constructive interference magnitude in
order to avoid a violation of the conservation of
energy principle. This is why a Z0-match works.

> Since one needs to know the constituent voltages to
> determine the sign of Pr.correction, why not just use
> superposition to compute the total voltage and then
> derive the power?

That is what has extended this discussion to arguments
over the past quarter century. That 30,000 foot method
says nothing about where the ExH energy in the reflected
wave goes. The irradiance (power density) equation with
its defined "interference term" tells us exactly where
all the energy goes and answers the question: What happens
to the ExH energy in the reflected wave?

Here are the basic principles:

When destructive interference occurs, there is "extra"
energy left over from that isolated event. That energy
must go somewhere. Here are the possibilities in a
typical lossless RF transmitting system.

1. The source can throttle back on its energy output
to compensate for the destructive interference energy.

2. Reactive components can store the destructive
interference energy and return it to the network at
a later time.

3. In the absence of (1) and (2) above, an RF energy
wave is launched in a direction that allows the
"extra" energy to leave the destructive event area.

The last possibility is why we can observe reflected
energy being redistributed back toward the load in
the complete absence of single-wave reflections.

When constructive interference occurs, there is "missing"
energy needed to be supplied into that isolated event. That
energy must come from somewhere. Here are the possibilities
in a typical lossless RF transmitting system.

1. The source can simply supply the energy needed by
the constructive interference event.

2. Reactive components can return stored energy to
the network.

3. In the absence of (1) and (2) above, constructive
interference energy *must* be supplied in real time
by destructive interference between two other waves.

****
* The last possibility is how a Z0-match redistributes *
* all of the reflected energy back toward the load when *
* the physical reflection coefficient is not 1.0. *
****

The two-step process of redistributing 100% of the ExH reflected
wave energy back toward the load is covered in my other energy
analysis article on my web page at:

http://www.w5dxp.com/energy.htm

> This analysis also makes clear the nature of powers
> computed from the constituent voltages of superposition.
> These powers do not represent real energy flows. As
> discussed far above, real energy flows can be summed
> to test for conservation of energy.

Translation: Don't bother trying to ascertain where the
ExH component wave energy goes. Since the conservation
of energy principle cannot be violated in reality, it
is OK to violate it conceptually. Now where have I
heard that argument before? :-)

"I personally don't have a compulsion to understand where
this power 'goes'."

Do you really think that the ExH energy in a reflection
from a mirror does not represent real energy flow?

Probably would work ok. The other approach would be a more conventional dipole looking thing, with the tuner in the middle. To a first order, they'll work the same. A long skinny (much << wavelength wide) loop looks a lot like a folded dipole. So, how well it works will probably be determined more by what impedance happens to appear at the feedline, and how well the tuner matches it. If the tuner's at the end (either of the skinny loop or a long random wire) then the impedance tends to be high (close to resonance). If it's in the middle, it's low.

In your situation, I might be tempted to try hanging a vertical wire down the side of the house, hooked to one side of the tuner, and the other horizontalish wire 6 ft off the roof. RFI/EMI might be an issue..

You could also do something like run a couple wires on the roof at right angles to the ridge line, hook those to one terminal of the tuner, then hook your wire running along the ridge to the other terminal.

I've fooled around a lot with various "throw the wire on the roof" situations (out of laziness, more than anything), and, in general, it seems to work better (no quantititive results) when it looks more like a fan dipole (feedpoint in the middle-ish) than a loop (feedpoint on the edge).

What you are missing is the localized interference patterns
within the individual cycles. The interference changes from
destructive to constructive every 90 degrees. For every
negative (destructive) interference term, there is an equal
magnitude positive (constructive) interference term 90 degrees
later. These, of course, average out to zero. Exactly the
same thing happens when a coil or capacitor is present in
a circuit. When the instantaneous voltage of a source is
zero and thus delivering zero instantaneous power, a
circuit capacitor is delivering energy back into the
circuit that can be dissipated by a resistor.

Power is certainly compressible. One can stuff 100 amphere-
hours into a battery in 2 hours and take 20 hours to remove it.
Why can't 60 watts of instantaneous power be stuffed into
a reactance and be removed 90 degrees later?

> I am not ready to suggest a cure for my traveling wave analysis. I
> only see that it does not work to my expectations.

Your expectations seem to be based on a conservation of
power principle which doesn't exist. There is no violation
of linearity if the energy dissipation is delayed by 90
degrees or by ten billion years.

I don't recall any published material where anyone tried
to explain where the instantaneous energy goes while at
the same time denying the possibility of interference.

This is still a strain in language as you have done nothing to
describe what the "compensation" is for. The circuit of your
schematic is fully differential in a bridge configuration, so saying
it will not amplify still makes no sense. To offer a deliberate
imbalance to a balanced circuit gives rise to astability which is the
first hallmark of oscillation - especially in an amplifier with too
much gain, and too much current drain - or a lockdown.

I get every impression that this bridge configuration arrived from
some sense of "ground" that then drove the need for the cross piece to
the midpoint of the loop. That point is "ground", but only as an
electrical neutral to the loop. It carries no other "ground"
distinction and you could have as easily built a single MOSFET
amplifier rather than a bridge configuration. A split shield around
the loop (or integrating it into the design) would have simplified AGC
and control lines too.

You tried to incorporate some of the split shield design into this
when you enclosed the amplifier and made a socket connection, but you
defeated the benefit of the choke at the same time with a zero net
gain (the choke, as built, has no use).

>> Sounds like a lot of unnecessary complexity. The one thing you repeat
>> is varicaps, but I don't see them.
>
>I have. I just did now how them because this is trivial.

They are not shown in your schematic. I don't see them in your
photos. Making them operational is adding yet more lines, although I
can see they would be necessary for your purposes.

Providing the decoupled varicap bias into a balanced circuit is not
trivial at all, and offers the prospects of returning to that self
oscillation. There will be something like half a dozen components for

that alone.

HOWEVER, this is all beside the point unless your design breaks into oscillation again. You haven't informed us how you cured that since you announced you had solve all your problems.

Double antennas deliver double the signal

The wireless shadows of tall buildings are a challenge for transmission.
PhotoDisc
Digital TV transmission techniques that deliver most benefit in the worst reception environments have been developed by a consortium of European researchers. The technologies promise to reduce the network infrastructure needed for mobile TV, while minimising the power demands and complexity of mobile TV receivers of the future.

In a typical broadcast transmission, radio signals bounce off objects in the environment, reaching the receiver over multiple paths. Distortion from ‘multi-path’ signals can produce fading, resulting in temporary failure of reception. Most of us have experienced this, moving a mobile phone around a room to get the strongest signal.

Modern broadband wireless technologies like wimax, DAB for audio, and DVB-T and DVB-H for video, use a modulation scheme called Orthogonal Frequency-Division Multiplexing (OFDM).

An OFDM transmission is spread across thousands of different sub-carriers, each carefully organised at slightly different frequencies within the channel. Spreading the transmission across a high number of sub-carriers increases the probability of maintaining error-free transmission.

Researchers have demonstrated that splitting the transmit power between multiple antennas can provide substantially more effective coverage than using a single antenna. Signal simulations carried out for project Pluto show a gain of up to 5 decibels could be achieved. The Physical Layer DVB Transmission Optimisation (PLUTO) project comprises a consortium of academics, equipment manufacturers, propagation experts and broadcasters from Finland, France, Germany and the UK, co-funded by the European Commission.
Best in worst environments

The transmission-splitting technique under development by PLUTO, known as ‘transmit diversity’, benefits the worst environments most. Reception can be spectacularly improved indoors, or whilst walking or driving in cities. Fewer transmitters and less power are required to achieve economical coverage.

“This technique does not require revision of any WiMAX, DVB or DAB standards,” says Maurice Bard of UK company Broadreach Systems, the

technical leader of PLUTO. “The great advantage is that it can be exploited by existing in-service receivers without modification. All you need is an additional box that can split the signal.”

“The transmit antennas need to be spatially separated by between 10 and 20 wavelengths and a delay applied to one antenna to achieve effective de-correlation. The amount of separation and delay depends on the type of environment to be covered,” says Bard.

Coverage can be further improved if there are two or more antennas at the reception end, he explains: “For receive diversity, you need to separate the receive antennas by at least half a wavelength which is approximately 25 centimetres at UHF frequencies. If this can be achieved, then transmit and receive diversity can work together to deliver even greater benefits. The benefits of receive diversity, however, can only be exploited in terms of network design if all receivers in the network have diversity implemented.”

Filling in black holes

Even with the reception improvements promised by transmit diversity, there will be reception black spots, particularly indoors, where on-channel repeaters will be needed. An on-channel repeater receives a signal from a distant transmitter and re-transmits it at the same frequency. The repeaters are prone to instability caused by the feedback of echoes from the transmitter to the receiver. Here, the academics at Brunel University, led by PLUTO project coordinator Professor John Cosmas, have developed an innovative method to remove these echoes.

A pseudo-random sequence is buried deep in the re-transmitted DVB-H signal,” explains Cosmas. “The sequence acts as a signature, allowing the repeater to differentiate the unwanted echoes from the wanted original signal and remove them from the re-transmission.”

“The method can work for repeaters of any OFDM based network.”

Broadreach Systems has provided equipment to process signals at the transmitter and monitoring stations that intercept and measure transmitted DVB signals. The monitor stations are networked to a control centre, developed by Brunel, enabling the effects of diversity to be evaluated in real time.”

There are still some hurdles to be overcome before PLUTO’s transmit diversity solution is suitable for all types of broadcast networks. Transmit diversity actually results in a degradation in reception where the receiver is in clear line-of-sight with the transmitter and the signals from each antenna are received at exactly the same power level.

The line-of-sight reception loss may not prove to be a problem for many networks. In a mobile TV network, all receivers will be in a non- or near-line-of-sight situation, very few will have rooftop antennas. But ‘good enough’ is not a position that the PLUTO consortium is prepared to stop at if they are to change traditional thinking.

“We need to show that the performance we saw in the lab can be achieved in all real situations, rain, snow, cities …” says Cosmas.

“And, we have to convince the broadcasters who designed traditional analogue networks, where multi-paths had to be avoided, that multi-paths are good.”

Leave it planted in the ground with all the radials for lightning
protection. Put a big top hat up there and gamma match it (the line
will probably run the full height). Press key to transmit.

I believe a better aproach is to not have the antennas separated by
half a WL
but to put them on the same axis i.e. altenate polarity selective.With
splitting based on
signal level it would be more ambidextrious.In a couple of weeks I
will be
situated to check this out!

add a top hat to it to help make it more efficient, that will definately help. base loading or tuner will be needed to make most radios happy with it, if you are going to use a tuner and the coax run isn't extremely long i wouldn't bother with base loading... unless you want to run high power where the swr on the cable may damage it, or your tuner just can't handle the mismatch.

Another point to reckon with is the tilted folded dipole
The experiment the Naval departgment under took when comparing
antennas.
The results showed that antennas tipped away from parallelism to the
ground
provided best results for their use which concentrated on receiving.
All existing antennas were removed and replaced by tilted radiators.
Thus their tests showed that tipped radiators was not a "myth" as
stated by this group
and also radiationis not primarily at right angles to a radiator.Is
the Navy at fault by not conforming
to Kraus's and other expert teachings and aligning themselves to
facts attained in the field.
As Reagan stated "Trust but verify" The same goes for students who
suck up what the experts
and professors state without verifying from first principles. Choice
of answers will
allow memorisation to pass the exam but not to arrive at the cusp of
new discoveries!

Go here and check out what the recent Clipperton Island DXpedition was
using on 160M: http://www.clipperton2008.org/dxpedition/antennas.htm

The photo of the 160M antenna is at the bottom of the web page.

It's basically your 60' vertical with a top hat consisting of four 46'
wires and a four 132' radials.

They had a good signal here in SoCal. The antenna inventory also
listed a balloon lifted vertical, but the operators were almost always
talking about the high winds and rain they experienced. I'll be
interested to find out if they were able to use the balloon at all
under those conditions.

It will not amplify signal in-phase signal. It's same like
differential amplifier.

> I get every impression that this bridge configuration arrived from

Yes. It's "Ground" only for bridge amplifier.

> distinction and you could have as easily built a single MOSFET
> amplifier rather than a bridge configuration. A split shield around

It's more difficult for me. It's looks more simply for me to build
fully symmetrical amplifier.

Hi,
Back at the start of the 80's, I had an article on how to build a
multi-band vertical from 4 inch pvc and 1/2 emt. I actually made one
and
it worked quite well, but one to many moves and 25 years later and it
and
the article are gone. I also remember that one of the amateur antenna
companies even made a version to sell. Anyways, if someone, could
remember the name or come up with a link, it would be greatly
appreciated.

>edge).

My original post was to generate topics on the antenna design and/or
equivalent or better stealth alternatives. I don't really need to
drop the wire, but that too is a good idea.

As for the 'fan dipole' you like, I have been using the horizontal
version throughout my 30 years of ham radio. I learned about the
two-wire version as a novice when I was first licensed. 80 meters cut
for the Novice frequencies also doubled as a 10 meter dipole. 40
meters cut at the lower end of the Novice frequencies doubled as a 15
meter antenna.

As a General Class operator, I discovered I not only had to add an
element for 20 meters, but the 75 meter dipole didn't work on 10 and
the 40 meter dipole didn't work on 15 meters ??? Then I learned about
where the harmonics fell.

By the time I became Advanced class, we had three new WARC bands.
Along with 75, 80, 40, 30, 20, 17, 15, 12, & 10 meters comes 9 wires
or an antenna tuner. I never did like antenna tuners. I always
wanted one antenna to do it all. It is amazing how quickly I fell in
love with my tuner, though, when I hung a 130 foot dipole about 100
feet high center fed with 300 ohm twin lead. I learned to tune the
antenna almost as quickly as I could throw an antenna switch a couple
of times.

Now that auto-tuners are about as inexpensive as the manual tuners, I
am awfully tempted to wander over to the SGC shelf at one of the ham
stores and try it out.

I am moving to a new house soon. We will be restricted in antennas
only to the extent that we don't make the yard look too ugly. It
isn't terribly well suited for many antennas, but I do hope to put up
at least one decent fan-dipole, more accurately parallel dipole. I
don't think I can fit a full-wave loop, due to lack of supports, but
it looks like I'll have a place outside my window where a row of trees
can support a 60 foot or so high dipole.... I still have a 100 foot
roll of 300 or 450 ohm window line :)

I guess I digressed.

A capacity hat will help, center loading may be easier to deal with
than top loading and the general rule is the more the better. (or
taller the better in your case.)

Good luck :)

Please see the US ARRL frequency chart here:

http://www.arrl.org/FandES/field/regulations/Hambands_color.pdf

7000 to 7050 MHz is RTTY and Morse code only. If you want voice,
probably SSB try 7125 to 7300 MHz.

If you have a 60 ft mast, I'd add a "T" top hat using two wires
that are about 60-70+ feet long each. That would load the
mast with no other coil loading needed. The top wires can
angle down a bit like an inv vee if the supports for the ends
are low. It's possible you may need some matching to the line.
But that can be a simple tapped coil like they use on mobile
whips. Top loading will make a large difference, not only to
reduce the coil loading needed, but it also improves current
distribution. Two wires for a hat are plenty. You will still see
a nearly perfect omni pattern from the antenna.

I'm in Europe. We have only 7000....7100.

3593. Hamstick dipole for 80m

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-25 12:05:13 UTC
From: JN <jnxx@vfemail.net>
Message-ID: <47e8e5d4$0$23840$9b536df3@news.fv.fi>
Source record: 26665

Hamsticks and their clones are for US 75m (4MHz) and not directly tunable to 80m (3,5 MHz)

I plan a Hamstick dipole for Digimodes and CW for say 3560 kHz.

What is the best way to lower the resonance frequency
Some type of capasitive loading at the end of base(coil) section
or an inductance at center wich could maybe also function as impedance transformer?
What is the feedpoint resistance of Hamstick dipole?

Any ideas or experiences?

Yes indeed. And what I have said, is that when this is
happening it is always possible to identify the element
which is storing the energy and provide the function
that describes the energy flow in and out of the
element. It is this identification and function that
I keep asking for to back up the handwaving claim that
you have been making.

Bzzt. Power is the rate of change of energy. The
quantity of energy can be dropping (i.e. negative power),
without the quantity of energy ever going below zero.

> Note there are no
> negative power signs in the power density equation
> where 'theta' is the phase angle between the two
> interfering voltages:
>
> Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(theta)

Unfortunately, I took a small shortcut in my last
post and left out the "(t)" from all the functions.
You immediately jumped to an RMS interpretation.

Please re-read all the equations with "(t)". There
is no "cos(theta)" factor when "(t)" is present.

> The last term is known as the "interference term",
> page 388 of "Optics" by Hecht, 4th edition. When

> indicating constructive interference. When theta = 90,
> there is zero interference which is what Part 1 of my
> web articles is based upon.

But this applies to RMS voltages and average powers.
You have extended this to instantaneous, for which a
"cos(theta)" factor is inappropriate.

> > This Pr.correction term has nothing to do with
> > interference, ...

> and "Coherency".

Read it as Pr.correction(t) to emphasize that it is not
average power of which I am writing. Then it is not
interference.

> > Note that there is no hint that Pr.correction needs to be

>
> You're correct, there's no hint. It is spelled out in
> detail in "Optics". The possibilities are listed below.
> Your above statement is a conceptual violation of the
> conservation of energy principle.

Of course not. Because the powers imputed to the
constituent voltages of superposition do not represent
actual energy flows. Conservation of energy only
applies to powers that represent actual energy flows.

> In the absence of
> any other energy source or energy sink, localized
> destructive interference must exactly match the
> localized constructive interference magnitude in
> order to avoid a violation of the conservation of

But you have to be cautious that you are applying
conservation to powers that represent actual energy
flows.

> to the ExH energy in the reflected wave?

It would be more valuable were you to thoroughly study
and understand what is happening in a transmission line
and then apply those learnings to ExH. The transmission
line is easier to understand. The voltages, currents and
time relationships can easily be precisely computed and
measured. Once you have gained a full understanding of
what power means in this easier to follow environment,
extend that understanding to the meaning of power in
an ExH, or optics environment where calculation and
measurement is much more difficult.

Or perhaps, these powers of which you speak do not
represent actual energy flows and therefore your
requirement that they need accounting is incorrect
and all of your attempts to explain them, unnecessary.

The difficulty of accounting for these powers is entirely
consistent with them not representing the actual flow
of energy.

> The last possibility is why we can observe reflected

This turns out, however, just to be an ideosyncracy of the math,
much like the way Pf-Pr is the actual energy flow in the transmission
line because of the way that Vf and Vr are derived from Vactual
and Iactual.

> > This analysis also makes clear the nature of powers

What can I say? That is what the math proves. The reflected power is a power computed from partial E and H fields that are being superposed, and we know that when you superpose, you need to compute the total voltage and current (or E and H) and then use that to compute the actual energy flow.

It would be good, if just for a day, you let go of the idea that Preflected represents an actual energy flow. Explore the actual measureable behaviour of transmission lines without using the idea that Preflected represents an actual energy flow.

Everything works. There is no violation of conservation of energy or any other fundamental physical law.

And the explanations are much simpler. You will no longer find the question "where does the reflected power go?" relevant. You can terminate your quest.

And as for "2*SQRT(P1*P2)cos(theta)", this will just be an idiosyncracy of the math that allows you to compute the total power, if you are presented with P1 and P2 (not being actual powers) that were computed from the constituent voltages of superposition; a useful tool when you can not measure the voltages (e.g. in optics), but not to be confused with reality.

Hi Cecil,

I feel better today. I think I have connected the dots and now have the spreadsheet showing that we really can use the traveling waves to solve the shorted transmission line problem on a instantaneous basis without the delay of energy into the next half cycle.

Here is a link to the new spreadsheet.

http://www.fairpoint.net/~rsparks/Smooth%20Power%20Reflection.pdf

I used the logic and formula presented in my post "Subject: Re: The Rest of the Story
Date: Thu, 20 Mar 2008 10:07:44 -0700"

You called it interference. Keith used your power equation and called the interference term a mathematical correction. It looks to me like the correction can be avoided by choosing the correct sin wave offset.

Ultimately, the waves can be resolved into one more powerful wave carrying the power described by Keith's "false power" equation. This is demonstrated in a spreadsheet found at

http://www.fairpoint.net/~rsparks/Reflect%20System%20Power.pdf

You need to take a look at the spreadsheets. I think they support the theory that we can track the power on an instant basis using traveling waves.

Was that the antenna with four vertical elements in a circle with the
four inch PVC for insulators and spacers?
If so it was in CQ magazine and I would have that in my collection
somewhere and could copy and email that to you.
Let me know..73 de VE3JUA

>
> Any ideas or experiences?

A hamstick has measured 12 dB down from a screwdriver
during 75m mobile CA antenna shootouts. That screwdriver
was about 10 dB down from a 1/2WL dipole. A 75m hamstick
is little better than a dummy load having a radiation
resistance of maybe 0.5 ohm and an efficiency in the
ballpark of 1%, i.e. 100 watts in, 1 watt out.

That said, the best way to accomplish what you are trying
to do is to use extenders on the bottom sections. The
longer the section underneath the coil, the greater the
radiation efficiency. I have extenders in 1, 2, 3, 4, 5,
and 6 foot lengths. They really come in handy for antenna
experiments.

If you could use 6 foot base extenders, that would make
the dipole 8+6+6+8 = ~28 feet long overall. Assuming you
could get that antenna up at a decent height (50+ feet),
I think the performance might be "not bad".

Hi Jouko:

I ran a ham stick dipole for a while and was able to compare it to a full size dipole when I put one up. To compare the two antennas, a ham stick dipole at 25 verses a full size dipole at 35. On 80/75m the ham stick was down about 20db from the dipole. The 2:1 SWR bandwidth was about 65KHz for the ham stick verses about 200+Khz for the dipole. The way to get a ham stick down the bottom of 80m is to lengthen the whip that sticks out the top. I can't remember how much but it was not much. The Z of a whip of the length of a ham stick should be only a few ohms, but they are close to 50 Ohms when used as a dipole. The difference between 50 Ohms and the modeled 2 to 3 Ohms is the loss in the coils. The long, small diameter coils made with small gage wire cause most of the loss. The ham stick dipole is better than no antenna but not by much on 80m. As you go up in frequency the performance of dipoles made out mobile antennas improve. On 40m my ham stick dipole was 12db down from a full size dipole and on 20m and above it was less than an S-unit down. Note that I'm talking about dipoles made out ham sticks made for the respective bands, not using a tuner. Using a turner is a waste of time as you move farther away from the center frequency the loss goes way up and your signal goes away! I still use my 80m ham sticks but not as dipole. I have them ground mounted with 4 10 radials each, spaced 1/16 wavelength apart and feed 90 deg. out of phase. This makes a directional receive antenna for the DX window on 80m that rivals a beverage antenna.

It makes DXing on 80m fun. The only disadvantage is that unlike a beverage it only works over about a 65Khz chunk of the band.

Good grief, Keith, do you not know how to track the
energy flow into and out of a reactance during an RF
cycle? Isn't that covered in EE201, "Alternating
Current Circuits", by Kerchner and Corcoran, 3rd
edition (c)1951? Quoting page 19:

"The implication is that the inductive element
receives energy from the source during one-quarter
of a cycle of the applied voltage and returns exactly
the same amount of energy to the driving source during
the next one-quarter of a cycle."

The equations are provided if you really need them.
Hint: A shorted 1/8WL stub is inductive.

> Bzzt. Power is the rate of change of energy.

Sorry, you are wrong about that.
From the IEEE Dictionary: "power - the rate of
generating, transferring, or using energy".

Power is a rate, not a rate of change. The
energy flow can be constant, i.e. rate of change
equal zero.

> Please re-read all the equations with "(t)". There
> is no "cos(theta)" factor when "(t)" is present.

I assume that exponential (phasor) notation for the
instantaneous values of the interfering voltages could
be used in which case there would indeed be a cos(theta)
present.

> But this applies to RMS voltages and average powers.
> You have extended this to instantaneous, for which a
> "cos(theta)" factor is inappropriate.

Nope, it's not. See above. Your same argument could
extend to the real part of phasors in which case you
could argue that the irradiance equation is bogus.
Good luck on that one. If the math didn't work, it
would have been discarded long ago and Hecht wouldn't
have an entire chapter devoted to "Interference".

> Read it as Pr.correction(t) to emphasize that it is not
> average power of which I am writing. Then it is not
> interference.

That statement makes it obvious that you don't understand
interference. When instantaneous values are being used,
if [V1(t)^2 + V2(t)^2] NOT= [V1(t) + V2(t)]^2, then
interference is present. Did you miss Physics 201?

> Because the powers imputed to the
> constituent voltages of superposition do not represent
> actual energy flows.

That statement is a violation of the wave reflection
model. Do you really believe that when you look
yourself in the mirror that those reflections are
devoid of energy? If so, please feel free to prove
your assertion.

> But you have to be cautious that you are applying
> conservation to powers that represent actual energy
> flows.

Reflected waves contain energy whether from your mirror
or from a mismatched load at the end of a transmission
line. You are arguing that the wave reflection model
is wrong. Please prove it.

> Or perhaps, these powers of which you speak do not
> represent actual energy flows and therefore your
> requirement that they need accounting is incorrect
> and all of your attempts to explain them, unnecessary.

Yes, perhaps the wave reflection model is wrong but
that makes your argument not with me, but with Ramo,
Whinnery, Johnson, Chipman, Slater, Hecht, and Walter
Maxwell. Good luck on winning that one.

> The difficulty of accounting for these powers is entirely
> consistent with them not representing the actual flow
> of energy.

No, it is perfectly consistent with a large degree
of ignorance which few people desire to alleviate.

Ignoring the role of interference and lumping all the
energy components into a mashed potato salad is one
method of sweeping everything under the rug so you
can ignore the problem instead of solving it.

> Or possibly, the premise that these powers represent
> actual energy flows is flawed.

Feel free to prove the wave reflection model wrong.

> This turns out, however, just to be an ideosyncracy of the math,
> much like the way Pf-Pr is the actual energy flow in the transmission
> line because of the way that Vf and Vr are derived from Vactual

Feel free to prove the math wrong.

> It would be good, if just for a day, you let go of the
> idea that Preflected represents an actual energy flow.

I will do that the day that you prove those reflections
from your mirror, that allow you to see yourself each
morning, contain zero energy. Your concepts seem more
like a religion than anything associated with reality.
Your mantra seems to be: "If I don't understand it,
it doesn't exist."

Things automotive seem to be favored. How about an exhaust system for
a radiator and a coil spring for a loading coil.

Jimmie

The ham stick dipole isn't very great for 80 meters. I know from
experience that the hustler mobile antenna works better than the ham
stick on 75 meters. I have used the ham stick on 80 meters mobile
